Abstract

Fractional Quantum Hall effect (FQHE) is a unique many-body phenomenon, which was discovered in a two-dimensional electron system placed in a strong perpendicular magnetic field. It is entirely due to the electron-electron interactions within a given Landau level. For special filling factors of the Landau level, a many-particle incompressible state with a finite collective gap is formed. Among these states, when the Landau level is half filled, there is a special FQHE state that is described by the Pfaffian function and the state supports charged excitations that obey non-Abelian statistics. Such a $1/2$ -FQHE state can be realized only for a special profile of the electron-electron potential. For example, for conventional electron systems the $1/2$ -FQHE state occurs only in the second Landau level, while in a graphene monolayer, no $1/2$ -FQHE state can be found in the first and the second Landau levels. Another type of low-dimensional system is the bilayer graphene, which consists of two graphene monolayers coupled through the interlayer hopping. The system is quasi-two-dimensional, which makes it possible to tune the inter-electron interaction potential by applying either the bias voltage or the magnetic field that is applied parallel to the bilayer. Interestingly, in the bilayer graphene with AB stacking, there is one Landau level per valley where the $1/2$ -FQHE state can indeed be present. The properties of that $1/2$ -FQHE state have a nonmonotonic dependence on the applied magnetic field and this state can be even more stable than the one discovered in conventional electron systems.

Key points

- In two-dimensional electron systems an externally applied magnetic field results in the formation of highly discrete and degenerate Landau levels.
- In a strong enough magnetic field, the discrete nature of the energy spectrum of two-dimensional electrons results in the integer quantum Hall effect (IQHE), which happens when integer number of Landau levels are occupied.
- For a partially filled Landau levels, inter-electron interactions result in formation of incompressible liquids, which manifest themselves as the Fractional Quantum Hall Effect (FQHE).
- The conventional FQHE corresponds to filling factors of type p/q , where q is odd.
- The unconventional FQHE at half-filling ($\nu = 1/2$) of a given Landau level is described by the Pfaffian function as the wave function of the ground state and has excitations with the charge of $e/4$ and obey non-abelian statistics.
- For conventional 2D systems, $1/2$ -FQHE is realized only in the $n = 1$ Landau level.
- For graphene monolayer, there is no $\nu = 1/2$ incompressible liquid in the first and second Landau levels.
- For bilayer graphene there is a special Landau level in which the stability of the $\nu = 1/2$ incompressible state can be tuned by the magnitude and direction of the magnetic field and the bias voltage.

Introduction

A moving charge placed in an external magnetic field experiences a magnetic force, which can change only the direction of the charge velocity but not its magnitude. One of the manifestations of this property of the magnetic field is the Hall effect. The Hall effect occurs when the current flows through a solid and the magnetic field is applied perpendicular to the current. In this case the voltage

difference, which is called the Hall voltage, is generated across the conductor in the direction transverse to both the current and the magnetic field. This effect was discovered by Edwin Hall in 1879 (Hall, 1879). If the electric current is in the x direction with the current density of j_x and magnetic field is in the z direction, then there is a Hall electric field generated in the y direction. The strength of the Hall effect is characterized by the Hall coefficient defined by the following expression (Ashcroft and Mermin, 1976; Hurd, 1972; Kittel, 2005)

$$R_H = \frac{E_y}{j_x B_z}. \quad (1)$$

It is possible to show that, within the classical approach, the Hall constant is related to the charge of the carriers, q , and their density, n ,

$$R_H = \frac{1}{nq}. \quad (2)$$

One important property of this expression is that the Hall constant and correspondingly the Hall voltage depends on the sign of carrier's charge, q . For example, for semiconductors, when the carriers are negatively charged electrons or positively charged holes, the Hall constant can be negative or positive depending on the type of the major carriers.

The above expression for the Hall coefficient corresponds to the classical description of the electron dynamics in a magnetic field, or in the low magnetic field limit. With increasing magnetic field, the electron dynamics in the magnetic field becomes essentially quantum mechanical, which results in quantization of the corresponding energy spectrum and formation of highly degenerate and discrete Landau levels (Landau and Lifshitz, 1965). The energy distance between the Landau levels is proportional to the magnetic field. Due to discrete nature of the energy spectrum of carriers, the diagonal resistance of a solid as a function of the magnetic field shows oscillations, which are called the Shubnikov de Haas oscillations (Seiler and Stephens, 1991).

More interesting and unexpected phenomena occur in two-dimensional (2D) electron systems, such as in heterojunctions, atomic monolayers, or in quantum wells. If the magnetic field is applied perpendicular to the 2D layer, i.e., the (x, y) plane, then for weak magnetic fields there is the classical Hall effect, which can be also characterized by the Hall resistance R_{xy}

$$R_{xy} = \frac{E_y}{j_x} = R_H B_z. \quad (3)$$

Therefore in the classical regime, i.e., in a weak magnetic field, the Hall resistance is proportional to the magnetic field, B_z . At the same time, in stronger magnetic fields when the quantization of the in-plane electron dynamics results in Landau levels, there is another unique effect, which is the Integer Quantum Hall Effect (IQHE) (Chakraborty and Pietiläinen, 1995; von Klitzing et al., 2020; Klitzing, 2017; Klitzing et al., 1980; Prange and Girvin, 1987; Stone, 1992; Yoshioka, 2002). In this regime, the Hall resistance takes only quantized values of the form

$$R_{xy} = \frac{h}{e^2 \nu}, \quad (4)$$

where h is the Planck constant, e is the electron charge, and ν is an integer, $\nu = 1, 2, 3, \dots$. The integer number ν corresponds to the number of completely filled Landau levels and whenever the Fermi energy is between the two Landau levels n and $n + 1$, the Hall resistance is constant, while the longitudinal resistance, R_{xx} , becomes zero. Strictly speaking, to understand the Quantum Hall Effect we also need to consider broadening of the Landau levels due to disorder and spatial localization of the in-gap electron states between the Landau levels (Chakraborty and Pietiläinen, 1995; Stone, 1992). However the main condition for the IQHE is the existence of the gaps in the energy spectrum which naturally occurs in 2D systems in a strong magnetic field.

The IQHE was discovered experimentally in 1980 and 2 years later another unexpected (and more spectacular) effect was observed in even stronger magnetic fields, and in better quality samples. This effect is known as the Fractional Quantum Hall Effect (FQHE) (Chakraborty and Pietiläinen, 1995; Tsui et al., 1982). In this case the filling factor ν in Eq. (4) is fractional and corresponds to partial occupation of a given Landau level, see Fig. 1. Since all levels within the Landau level are degenerate, the electron-electron interaction completely determines the properties of the system. At special fractional occupations of the Landau level, the interaction generates the incompressible ground states with gapped excitations, which finally results in the FQHE. The primary filling factors where the FQHE occur are $\nu = \frac{1}{3}, \frac{2}{3}, \frac{1}{5}, \frac{2}{5}, \frac{3}{5}, \frac{1}{7}$ etc. (Chakraborty and Pietiläinen, 1995; Halperin and Jain, 2020; Prange and Girvin, 1987). In all these cases the denominator is an odd number, which is due to the fermionic nature of electrons.

Fractional quantum Hall effect

First, we consider the conventional two-dimensional electron systems, such as the ones grown in heterojunctions or in a quantum well, for which the low-energy dispersion relation is parabolic. The Hamiltonian of such systems has the form

$$\mathcal{H}_c = \frac{\vec{p}^2}{2m^*}, \quad (5)$$

where $\vec{p}$ is the two-dimensional momentum and m^* is the electron effective mass. When the system is placed in a perpendicular external magnetic field, the Hamiltonian becomes

Fig. 1 Non-diagonal and diagonal resistivities, ρ_{xy} and ρ_{xx} as a function of the magnetic field, B . The sample is GaAs—Al_{0.3}Ga_{0.7}As with electron density of $n = 1.23 \times 10^{11} \text{ cm}^{-2}$ and mobility $\mu = 90,000 \text{ cm}^2/\text{Vs}$. Adapted from Tsui DC, Stormer HL, and Gossard AC (1982) Two-dimensional magnetotransport in the extreme quantum limit. *Physical Review Letters* 48: 1559–1562, doi:10.1103/PhysRevLett.48.1559.

$$\mathcal{H}_c = \frac{\vec{\pi}^2}{2m^*}, \quad (6)$$

where $\vec{\pi} = \vec{p} + e\vec{A}/c$ is the generalized momentum and $\vec{A}$ is the vector potential. The energy spectrum of the Hamiltonian (6) consists of highly degenerate discrete Landau levels (Landau and Lifshitz, 1965) with energy

$$\epsilon_n = \hbar\omega_B \left(n + \frac{1}{2} \right), \quad (7)$$

where $\omega_B = eB/m^*$ is the cyclotron frequency and $n = 0, 1, 2, \dots$ is the Landau level index. We write the corresponding Landau eigenfunctions as $\phi_{n,m}$, where the index m labels the degenerate wavefunctions within a given Landau level and is determined by the choice of the gauge. For example, in the Landau gauge, $A_x = 0$ and $A_y = Bx$, the index m is the y -component of the momentum, while in the symmetric gauge, $\vec{A} = \frac{1}{2}\vec{B} \times \vec{r}$, the index m is the z -component of electron angular momentum (Landau and Lifshitz, 1965). In what follows, we consider m as the z component of the angular momentum.

When a given Landau level is partially occupied by electrons, the properties of the system is completely determined by the electron-electron interactions. If the mixing of Landau levels due to the interactions is weak, then the interaction properties of electrons within a single Landau level are completely determined by the Haldane pseudopotentials $V_m^{(n)}$ (Haldane, 1983). The Haldane pseudopotential $V_m^{(n)}$ is the energy of two electrons with the relative angular momentum m and they can be found from the following expression (Haldane, 1987)

$$V_m^{(n)} = \int_0^\infty \frac{dq}{2\pi} q V(q) [F_n(q)]^2 L_m(q^2) e^{-q^2}, \quad (8)$$

where $L_m(x)$ are the Laguerre polynomials, $V(q) = 2\pi e^2/(\kappa\ell_0 q)$ is the Coulomb interaction in the momentum space, κ is the background dielectric constant, and $F_n(q)$ is the form factor of the n -th Landau level. The form factor is totally determined by the structure of the wavefunctions of the corresponding Landau level. Different two-dimensional systems, such as the graphene monolayer, transition-metal dichalcogenide monolayer, graphene bilayer, etc., have different form factors $F_n(q)$, but in all cases,

the corresponding Haldane pseudopotentials are given by the same expression (8). For conventional two-dimensional electron systems with Landau wavefunctions $\phi_{n,m}$ the form factor is (Haldane, 1987)

$$F_n(q) = L_n(q^2/2). \quad (9)$$

If the electron system is fully spin polarized then the spatial component of the many-particle wavefunction is antisymmetric with respect to the particle exchange. In this case, only the Haldane pseudopotentials, $V_m^{(n)}$, with odd values of m , $m = 1, 3, 5, \dots$, determine the properties of the system. The nature of the ground state mainly depends on the ratio of the first few pseudopotentials, $V_1^{(n)}/V_3^{(n)}$ and $V_3^{(n)}/V_5^{(n)}$.

At special values of the filling factor ν , which is defined as $\nu = N_e/N_0$, where N_e is the number of electrons in a given Landau level and N_0 is its degeneracy, the electron system becomes incompressible with a finite excitation gap. This incompressibility is entirely due to electron-electron interactions and is determined by the values of the Haldane pseudopotentials. Only for these filling factors the FQHE can be observed.

The conventional FQHE occurs at the filling factors of the form p/q , where q is odd, which is related to the antisymmetric property of a many-particle electron wavefunction when two particles are interchanged, i.e., $\Psi(\vec{r}_1, \vec{r}_2, \vec{r}_3, \dots) = -\Psi(\vec{r}_2, \vec{r}_1, \vec{r}_3, \dots)$. A prominent example of this type of FQHE is the $1/q$ sequence, i.e., $1/3, 1/5$ etc. The corresponding many-particle wave function is well described by the Laughlin function (Laughlin, 1983) of the form

$$\Psi(z_1, z_2, z_3, \dots) = \prod_{i < j} (z_i - z_j)^q \exp\left(-\sum_i \frac{z_i^2}{4\ell_0^2}\right), \quad (10)$$

where the positions of electrons are described in terms of complex variable $z = x - iy$, and $\ell_0 = \sqrt{\hbar/eB}$ is the magnetic length. The Laughlin function (10) corresponds to the filling factor $1/q$ and is very close to the exact many-particle wave function of the system. The accuracy of the trial wave functions, for instance the Laughlin function, is tested through numerical calculations for a finite-size electron system. For a finite-size system placed in an external magnetic field, the many-particle basis is finite, which allows us to find both the ground state and the excitation spectrum of the system. Then, the overlap of the trial function with the exact ground state wave function of the many-particle system can be determined and that can be used to test the accuracy of the trial approximation. The incompressibility of the system is determined by the magnitude of the gap in the collective excitations of the system. Another interesting property of the $1/q$ FQHE, which is described by the Laughlin function, is that the charged excitations have fractional charge $e^* = e/q$. For example, for the $1/3$ -FQHE the quasiparticles carry a fractional charge $e^* = e/3$.

Our fundamental understanding of the origin of the odd-denominator FQHE is from the brilliant work of Laughlin which requires that we consider a *incompressible* fluid that has no long-range positional order. The incompressibility implies that all the excited states have a non-zero energy difference from the ground state. The ground state can be fully spin polarized or also have spin degree of freedom (Apalkov et al., 2001; Chakraborty et al., 1986; Chakraborty and Zhang, 1984) in the ground state and spin-reversed excitations. It is worth emphasizing that despite the torrent of ideas unleashed by the Laughlin function, the origin of incompressibility in the Laughlin state still remains unresolved (Haldane, 2011).

In addition to the conventional FQHE set of type p/q , where q is odd, another type of FQHE corresponding to the filling $5/2$ has been discovered experimentally (Willett et al., 1987; Willett, 2013). This filling factor implies that there are two completely occupied Landau levels, which correspond to spin-up and spin-down Landau levels with index $n = 0$, and the next Landau level is half-filled. It means that in the $n = 1$ Landau level the $1/2$ -FQHE occurs, i.e., the filling factor of the $n = 1$ Landau level is $\nu = 1/2$. This unusual FQHE cannot be described by the Laughlin function (10). This is because the many-particle wave function should be antisymmetric with respect to the particle interchange, because the corresponding electrons are fermions and therefore q must be an odd integer. But for $q = 2$, the Laughlin function is symmetric, and therefore describes a system of bosons. Another important property of the $1/2$ -FQHE is that the $1/2$ incompressible liquid is realized only in higher Landau levels, for example, for $n = 1$ but not for the $n = 0$ level. Different wavefunctions (albeit a modification of the Laughlin state) have been proposed theoretically to describe this state. Among them are the Pfaffian (Moore and Read, 1991), anti-Pfaffian (Levin et al., 2007), particle-hole symmetric Pfaffian (Son, 2015), and the 221-parton (Wen, 1991) wavefunctions. The $1/2$ -FQHE is also sensitive to the inter-Landau level mixing (Rezayi, 2017) which modifies the electron-electron interaction potential (Peterson and Nayak, 2013) and opens up the possibility to observe the $1/2$ -FQHE in higher Landau levels (Kim et al., 2019) where the inter-Landau mixing becomes strong. Below we consider the properties of the $1/2$ -FQHE, which is described only by the Pfaffian wavefunction.

Pfaffian function

Some properties of the FQHE states can be understood by looking at the specially created composite objects, that are called the composite fermions. The composite fermion is an electron with an even number of flux quanta attached to it. These objects still have the same Fermi statistics as original electrons, but they feel a different magnetic field. To understand their properties, first, let us consider a fully filled Landau level. In this case, there is one magnetic flux quantum per each electron and under this condition we have the IQHE. Now let us consider a Landau level with the filling factor of $\nu = 1/3$, i.e., only $1/3$ states within a given Landau level are occupied. For such a system, there are three magnetic flux quanta per electron and this state corresponds to the $\nu = 1/3$ -FQHE. The composite fermions for this system are electrons bound to two magnetic flux quanta each. Therefore, for these composite fermions (one electron plus two flux quanta), there is one magnetic flux quanta per fermion, which corresponds to a fully occupied

Landau level and is therefore, the IQHE of composite fermions. Another way to state this is that, the FQHE for electrons is the IQHE for composite fermions. This correspondence exists only for the FQHE of type of p/q , where q is odd. As an example, for $\nu = 1/5$ the composite fermion is an electron plus four magnetic flux quanta and the composite fermions all occupy the first Landau level. It is important that the number of magnetic flux quanta attached to an electron is even. Only in this case the composite particles have the same Fermi statistics as electrons.

A unique situation occurs for the Landau level that is exactly half filled. For such a system, the composite fermion picture dictates that there are two magnetic flux quanta associated with each electron. In that case, a composite fermion comprise of an electron bound to two magnetic flux quanta and in a mean-field picture, the system of composite fermions does not experience a net magnetic field (Halperin et al., 1993). The properties of this composite fermion system are determined by the inter-fermion interaction, i.e., by the Haldane pseudopotentials. For the $n = 0$ Landau level, the composite fermions form a gapless composite Fermi liquid. A more interesting situation happens for the $n = 1$ Landau level, i.e., for the total filling factor $\nu = 5/2$. In this case, the theoretical and experimental results suggest that the system forms a gapped state which is due to pairing* of the composite fermions, i.e., by formation of Cooper pairs, similar to what we see in the superconductor systems. The pairing symmetry can then be different and below we consider only one type of symmetry, i.e., when the Cooper pairs of composite fermions have angular momentum -1 . It was proposed that the corresponding ground state of the system expressed in terms of the coordinates of original electrons is described by the Pfaffian (Greiter et al., 1991, 1992; Moore and Read, 1991; Nayak et al., 2008) function, which has the following form

$$\Psi_{\text{Pf}} = \text{Pf} \left[\frac{1}{z_i - z_j} \right] \prod_{i < j} (z_i - z_j)^2 \exp \left(- \sum_i \frac{z_i^2}{4\ell_0^2} \right), \quad (11)$$

where the Pfaffian is defined as (Greiter, 2011; Moore and Read, 1991)

$$\text{Pf} [\mathbf{M}] = \frac{1}{2^{N/2} (N/2)!} \sum_{\sigma \in S_N} \text{sgn } \sigma \prod_{l=1}^{N/2} M_{\sigma(2l-1)\sigma(2l)}, \quad (12)$$

for an $N \times N$ antisymmetric matrix $\mathbf{M}$ whose elements are M_{ij} , where N is an even number. Here S_N is the group of permutations of N objects. The rest of the right-hand terms in (11) corresponds to a fully *spin-polarized* (Chakraborty and Pietiläinen, 1988) Laughlin state (10) for $q = 2$.

Historically, the concept of Pfaffians arose from a very surprising mathematical result: Consider the determinant of a $N \times N$ antisymmetric matrix $\mathbf{M} = [M_{ij}]$ written as $\det[M_{ij}]_{1 \leq i, j \leq N}$ in which $M_{ij} = -M_{ji}$ for $i, j = 1, 2, \dots, N$. If $\mathbf{M} = -\mathbf{M}^T$ is an antisymmetric matrix of order N then $\det[\mathbf{M}] = (-1)^N \det[\mathbf{M}]$ so that if the order is odd, then the determinant vanishes. However, when $N = 2m$, then the determinant is the square of a polynomial in coefficients of the given determinant. This result was first discovered by the British mathematician Arthur Cayley in 1847 (Cayley, 1847; Halton, 1966), who named this polynomial *Pfaffian* in honor of the great German mathematician Johann Pfaff, who discovered it in 1815, in the course of his work on differential equations.

For $N = 2$,

$$\det \begin{vmatrix} 0 & M_{12} \\ -M_{12} & 0 \end{vmatrix} = (M_{12})^2, \quad (13)$$

and the Pfaffian is $\text{Pf} [\mathbf{M}] = M_{12}$. Similarly, for $N = 4$,

$$\det \begin{vmatrix} 0 & M_{12} & M_{13} & M_{14} \\ -M_{12} & 0 & M_{23} & M_{24} \\ -M_{13} & -M_{23} & 0 & M_{34} \\ -M_{14} & -M_{24} & -M_{34} & 0 \end{vmatrix} = (M_{12}M_{34} - M_{13}M_{24} + M_{14}M_{23})^2, \quad (14)$$

and the corresponding Pfaffian is

$$\text{Pf} [\mathbf{M}] = M_{12}M_{34} - M_{13}M_{24} + M_{14}M_{23}. \quad (15)$$

There are three terms in the above expression. For a general antisymmetric matrix $N \times N$, the number of terms in the Pfaffian is $(N-1)!!$. The Pfaffians are sometimes referred to as triangular determinant or half-determinant (Crilly, 2016),

$$\text{Pf} [\mathbf{M}] = \begin{vmatrix} M_{12} & M_{13} & M_{14} \\ & M_{23} & M_{24} \\ & & M_{34} \end{vmatrix}. \quad (16)$$

Moving on, one can obtain the following relation between the determinant of the matrix $\mathbf{M}$ and its Pfaffian (Cayley, 1847; Halton, 1966),

$$\det [\mathbf{M}] = (\text{Pf} [\mathbf{M}])^2. \quad (17)$$

*Pairing of electrons in order to form a Laughlin state of bosons was first proposed by Halperin in his classic paper (Halperin, 1983).

This relation can be generalized for a special partially antisymmetric matrix of the form (Bajdich et al., 2008; Cayley, 1847)

$$\det \begin{bmatrix} 0 & b_{12} & b_{13} & \dots & b_{1N} \\ -a_{12} & 0 & a_{23} & \dots & a_{2N} \\ -a_{13} & -a_{23} & 0 & \dots & a_{3N} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -a_{1N} & -a_{2N} & -a_{3N} & \dots & 0 \end{bmatrix} = \text{Pf} \begin{bmatrix} 0 & a_{12} & a_{13} & \dots & a_{1N} \\ -a_{12} & 0 & a_{23} & \dots & a_{2N} \\ -a_{13} & -a_{23} & 0 & \dots & a_{3N} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -a_{1N} & -a_{2N} & -a_{3N} & \dots & 0 \end{bmatrix} \times \text{Pf} \begin{bmatrix} 0 & b_{12} & b_{13} & \dots & b_{1N} \\ -b_{12} & 0 & a_{23} & \dots & a_{2N} \\ -b_{13} & -a_{23} & 0 & \dots & a_{3N} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -b_{1N} & -a_{2N} & -a_{3N} & \dots & 0 \end{bmatrix} \quad (18)$$

Other useful relations, involving Pfaffians of $N \times N$ matrices $\mathbf{M}$ and $\mathbf{A}$, are the following

$$\text{Pf} [\mathbf{M}^T] = (-1)^{N/2} \text{Pf} [\mathbf{M}] \quad (19)$$

$$\text{Pf} [\lambda \mathbf{M}] = \lambda^{N/2} \text{Pf} [\mathbf{M}] \quad (20)$$

$$\text{Pf} [\mathbf{A} \mathbf{M} \mathbf{A}^T] = \det [\mathbf{A}] \text{Pf} [\mathbf{M}]. \quad (21)$$

$$\text{Pf} \begin{bmatrix} 0 & \mathbf{M} \\ -\mathbf{M}^T & 0 \end{bmatrix} = (-1)^{N(N-1)/2} \det [\mathbf{M}] \quad (22)$$

$$\text{Pf} \begin{bmatrix} \mathbf{M}_1 & 0 \\ 0 & \mathbf{M}_2 \end{bmatrix} = \text{Pf} [\mathbf{M}_1] \text{Pf} [\mathbf{M}_2] \quad (23)$$

There is also a special expression for the Pfaffian of skew-symmetric tridiagonal matrix,

$$\text{Pf} \begin{bmatrix} 0 & a_1 & 0 & 0 & & \\ -a_1 & 0 & 0 & 0 & & \\ 0 & 0 & 0 & a_2 & & \\ 0 & 0 & -a_2 & 0 & & \\ & & & & \ddots & \\ & & & & & 0 & a_{N/2} \\ & & & & & -a_{N/2} & 0 \end{bmatrix} = a_1 a_2 \dots a_{N/2} \quad (24)$$

Pfaffians actually describe a *pairing* state. In fact, the famous Bardeen-Cooper-Schrieffer (BCS) wave function that is the wavefunction for spin-singlet pairs can be expressed in terms of the Pfaffians or a determinant (Bajdich et al., 2008; Bouchaud et al., 1988).

The Pfaffian function (11) which determines the $\nu = 1/2$ state is defined only for *even* number of particles, which illustrates its fundamental property as a collective state of the Cooper pairs, i.e., the bound state of two electrons. Interestingly, while the Pfaffian itself, i.e., the first factor in Eq. (11), is singular when two electrons are at the same position ($z_i = z_j$), when multiplied by the second factor, the Pfaffian function (11) becomes regular. In other words, the Pfaffian state has a nonzero amplitude at the coincidence of two particles. As an example, for four electrons the Pfaffian function takes the following form

$$\Psi_{\text{Pf}} = \left[\frac{1}{z_1 - z_2} \frac{1}{z_3 - z_4} - \frac{1}{z_1 - z_3} \frac{1}{z_2 - z_4} + \frac{1}{z_1 - z_4} \frac{1}{z_2 - z_3} \right] \times (z_1 - z_2)^2 (z_1 - z_3)^2 (z_1 - z_4)^2 (z_2 - z_3)^2 (z_2 - z_4)^2 (z_3 - z_4)^2 \exp \left(- \sum_i \frac{z_i^2}{4\ell_0^2} \right). \quad (25)$$

One can see that the highest power of any z_i , e.g., z_1 , in the above expression is 5. In general, for the number of electrons N_e , the highest power is $2N_e - 3$. In the thermodynamic limit, it gives the required filling factor $1/2$.

The Pfaffian state has a very unique property in terms of the charged excitations. In fact, the function that describes creation of two positively charged holes has the following form

$$\Psi_{\text{Pf}} = \text{Pf} \left[\frac{(z_i - \eta_1)(z_j - \eta_2) + (z_j - \eta_1)(z_i - \eta_2)}{z_i - z_j} \right] \prod_{i < j} (z_i - z_j)^2 \exp \left(- \sum_i \frac{z_i^2}{4\ell_0^2} \right). \quad (26)$$

Here η_1 and η_2 are the coordinates of the holes. The charge of these excitations is fractional, $e^* = e/4$, and they obey the ‘non-Abelian’ statistics (Nayak et al., 2008; Stern, 2008; Stern and Halperin, 2006). The non-Abelian statistics means that when two excitations exchange their positions, it changes not only the phase of the wave function but also introduces an unitary transformation of the wave function itself. In general, those unitary transformations do not commute and the system of those excitations is called non-Abelian.

The charged excitations of the Pfaffian state also carry the signature of Majorana fermions (MFs) (Ivanov, 2001; Read and Green, 2000). The Majorana fermion is a special type of ‘particle,’ which can be seen as its own anti-particle. If γ_i is an operator corresponding to the Majorana fermion i , then it satisfies the relations

$$\{\gamma_i, \gamma_j\} = 2\delta_{ij} \quad (27)$$

$$\gamma_i^\dagger = \gamma_i, \quad (28)$$

where $\{\gamma_i, \gamma_j\}$ is the anti-commutator of γ_i and γ_j . The first relation determines that these particles are fermions and the second relation tells us that the particle is its own anti-particle. The Majorana particle can be formally expressed as a combination of the creation, $c_i^\dagger$, and annihilation, c_i , operators of regular fermions,

$$\gamma_i = c_i + c_i^\dagger. \quad (29)$$

It means that the Majorana operator creates simultaneously a particle, e.g., an electron with the negative charge $-e$, and an anti-particle, e.g., a hole with positive charge e . In conventional systems such an operation is impossible, but in systems such as the superconductors which support Cooper pairs and for which the electric charge is conserved mod 2, the Majorana fermions are possible. Superposition of two Majorana fermions correspond to a fermionic state where the constituent MFs are spatially separated. This intrinsic non-local nature of the fermionic state makes the state resilient against errors caused by local perturbations from the environment (Ivanov, 2001). This property and the associated non-abelian exchange statistics makes the MFs well suited for fault-tolerant quantum computing (Ayukaryana et al., 2021; Das Sarma et al., 2005; Kitaev, 2003).

Many numerical studies of the $\nu = 1/2$ state have been performed in the spherical geometry (see, e.g., Fano et al., 1986; Haldane, 1983; Haldane and Rezayi, 1985). In this geometry, the electrons are placed on a surface of a sphere and the magnetic field is created by a magnetic monopole placed at the center of the sphere. The strength of the magnetic field is characterized by the parameter S , where $2S$ is the number of magnetic fluxes through the sphere in units of the flux quantum. At the same time the parameter S is equal to the angular momentum of single-particle states. All single-particle states have the same energy and form the Landau level, where different states are distinguished by the z component of the angular momentum. Therefore, in spherical geometry, the total number of states in the Landau level is $2S + 1$. In a many-electron system the electron-electron interaction is introduced through the Haldane pseudopotentials and the number of electrons, N_e determines the filling factor of the Landau level. Here the $\nu = 1/2$ FQHE corresponds to the following condition: $2S = 2N_e - 3$. Although in this case the ratio of the number of electrons and the number of single-particle states is not $1/2$, i.e., $N_e/(2S + 1) = N_e/(2N_e - 2) \neq 1/2$, for this value of S , the system has a gap and the ground state wave function is close to the Pfaffian function. In the thermodynamic limit, i.e., for $N_e \rightarrow \infty$, there is a correct identity $N_e/(2S + 1) = N_e/(2N_e - 2) \rightarrow 1/2$.

The position of an electron in spherical geometry can be described by either the two angles, ϕ and θ , or two components of a spinor, $u = \cos \theta \sin \phi$ and v . In terms of the variables u and v , the Pfaffian function takes the following form

$$\Psi_{\text{Pf}} = \text{Pf} \left[\frac{1}{u_i v_j - u_j v_i} \right] \prod_{i < j} (u_i v_j - u_j v_i)^2. \quad (30)$$

In the spherical geometry the Pfaffian function is an exact wave function of the ground state for the system with three-particle interaction defined as

$$H_{\text{int}} = \frac{e^2}{\kappa \ell_0} \sum_{i < j < k} P_{ijk} (3S - 3), \quad (31)$$

where P_{ijk} is the three-particle projection operator onto the state with the total angular momentum L .

In a planar geometry, the Pfaffian function is the exact ground state wave function of the system with the three-body interaction (Greiter et al., 1991, 1992) given by the following expression

$$H_{3B} = V_0 \sum_{i < j < k}^{N_{el}} S_{ijk} \nabla_i^2 \delta(i - j) \delta(i - k), \quad (32)$$

where $\delta(i - j) = \delta(\vec{r}_i - \vec{r}_j)$ is the δ function, ∇_i is the partial derivative with respect to $\vec{r}_i$, and S_{ijk} denotes symmetrization over permutations within (ijk) : $S_{123} = f_{123} + f_{231} + f_{312}$, and f is symmetric in its first two indices. To understand why for the three-body interaction potential (32) the energy of the Pfaffian state is zero, we need to look at the structure of the Pfaffian wave function. For example, by looking at the four-particle system (see Eq. (25)) we can see that the terms with z_1 are of the type: $(z_1 - z_2)(z_1 - z_3)(z_1 - z_4)^2 \dots$. Therefore, they have one factor with linear dependence on z_1 , $(z_1 - z_2)$, and all other factors have quadratic dependence on z_1 , $(z_1 - z_3)^2(z_1 - z_4)^2 \dots$. Now let us consider the term in the three-particle Hamiltonian (32): $\nabla_1^2 \delta(1 - 2) \delta(1 - 3)$. In order to find the contribution to the energy due to that term, we need to calculate the second derivative of $(z_1 - z_2)(z_1 - z_3)^2(z_1 - z_4)^2 \dots$ with respect to z_1 and then set z_1 equals to z_2 and z_3 , which finally gives us zero. Analyzing different terms both in the Hamiltonian (32) and the Pfaffian wave function, we can conclude that the energy of the Pfaffian state is zero and it is an eigenfunction of the three-particle Hamiltonian (32).

For the real two-body interaction, whether the Pfaffian function is the ground state wave function or not is determined by the values of Haldane pseudopotentials, mainly by the values of V_1/V_5 and V_3/V_5 . The diagram, which shows under what values of these parameters the half-filled Landau level becomes incompressible and is described by the Pfaffian function, is shown in Fig. 2 (Storni et al., 2010). The diagram depicts the contour plot of the gap of the system, where for the compressible state the gap is zero. The gap also characterizes the stability of the corresponding $1/2$ -FQHE state. Here the blue region corresponds to the compressible state, which does not support the $1/2$ -FQHE. The maximum overlap of the ground state wave function with the Pfaffian function is marked by a solid black line.

The thick lines with dots correspond to the conventional electron system with parabolic energy dispersion and different thickness of the 2D layer. Here the thickness of the layer changes the Haldane pseudopotentials, resulting in the corresponding

Fig. 2 Contour plot of the FQHE gap as a function of V_1/V_5 and V_3/V_5 . The black line marks the maximum of the overlap of the ground state wave function and the Pfaffian function. The lines with dots depict the effect of the finite width of a 2D layer. Here the red line corresponds to filling factor $\nu = 5/2$, which is the same as $\nu = 1/2$ at the $n = 1$ Landau level, while the blue line corresponds to $\nu = 1/2$ at the $n = 0$ Landau level. The dots denote the width $w/\ell_0 = 0, 1, 2, 3, 4$ (from right to left). The compressible region is shaded blue. Reproduced with permission from Storni M, Morf RH, and Das Sarma S (2010) Fractional quantum hall state at $\nu = 5/2$ and the Moore-read Pfaffian. *Physical Review Letters* 104: 076803, doi:10.1103/PhysRevLett.104.076803.

lines in the diagram. The results of Fig. 2 clearly show that, for the conventional system, the state in the half-filled $n = 0$ Landau level is compressible, while that for the half-filled $n = 1$ Landau level is incompressible and the overlap of the ground state wave function with the Pfaffian function is large. The half-filled $n = 1$ Landau level corresponds to the total filling factor of $5/2$.

The diagram shown in Fig. 2 can be also used to analyze the properties of half-filled Landau levels for other systems, such as the graphene monolayer and the graphene bilayer. The Haldane pseudopotentials for these systems are different from the ones for the conventional electron system.

The effective electron-electron interaction potential also depends on the Landau level mixing. This mixing can be important for systems with small Landau level gaps, such as the ZnO quantum wells (Luo and Chakraborty, 2017). The strength of this mixing is determined by the ratio of the Coulomb interaction and the Landau level gap. When this ratio is varied, it was shown by numerical analysis (Luo and Chakraborty, 2017) that, in the ZnO quantum well systems the topological transitions can be observed for the half-filled Landau level. Further, in ZnO systems a stable Pfaffian state have been predicted at filling factors $5/2$ and $7/2$ (Luo and Chakraborty, 2017).

Monolayer and bilayer graphene in a strong magnetic field

Graphene monolayer

Graphene is a single layer of carbon atoms (Novoselov et al., 2004; Wallace, 1947), which form the 2D honeycomb crystal structure with two sublattices, say A and B [see Fig. 3A] (Abergel et al., 2010). The corresponding electron band structure has two valleys at two inequivalent points, $K = (2\pi/a)(\frac{1}{3}, \frac{1}{\sqrt{3}})$ and $K' = (2\pi/a)(\frac{2}{3}, 0)$, in the reciprocal space [see Fig. 3B]. Here $a = 0.246$ nm is the lattice constant. The unique property of graphene is that the low-energy dispersion at each valley is determined by the massless Hamiltonian of the Dirac type (Dirac fermions) (Abergel et al., 2010; Castro Neto et al., 2009; Geim and Novoselov, 2007)

$$\mathcal{H}_\xi = \xi v_F \begin{pmatrix} 0 & p_- \\ p_+ & 0 \end{pmatrix}, \quad (33)$$

Fig. 3 (A) Honeycomb crystal structure of a graphene monolayer. Two equivalent sublattices A and B are marked by open and filled dots. (B) The first Brillouin zone of monolayer graphene. Two valleys K and K' are also shown.

where ξ is the valley index, which is 1 at the K valley and -1 at the K' valley, $p_- = p_x - ip_y$, $p_+ = p_x + ip_y$, and $v_F \approx 10^6$ m/s is the Fermi velocity. The corresponding eigenfunctions of the Hamiltonian (33) have two components due to two sublattices, A and B , of the graphene honeycomb lattice. The wave functions are expressed as $(\psi_A, \psi_B)^T$ for valley K and $(\psi_B, \psi_A)^T$ for valley K' , where ψ_A and ψ_B correspond to sublattices A and B , respectively.

The Landau level of electrons in graphene can be found from Hamiltonian (33) by replacing the electron momentum $\vec{p}$ with the generalized momentum $\vec{\pi} = \vec{p} + e\vec{A}/c$,

$$\mathcal{H}_\xi = \xi v_F \begin{pmatrix} 0 & \pi_- \\ \pi_+ & 0 \end{pmatrix}. \quad (34)$$

Then the eigenfunctions of the Hamiltonian (34) have the following form

$$\Psi_{n,m}^K = \begin{pmatrix} \psi_A \\ \psi_B \end{pmatrix} = C_n \begin{pmatrix} \text{sgn}(n) i^{|n|-1} \phi_{|n|-1,m} \\ i^{|n|} \phi_{|n|,m} \end{pmatrix}, \quad (35)$$

for the valley K ($\xi = 1$) and

$$\Psi_{n,m}^{K'} = \begin{pmatrix} \psi_B \\ \psi_A \end{pmatrix} = C_n \begin{pmatrix} \text{sgn}(n) i^{|n|-1} \phi_{|n|-1,m} \\ i^{|n|} \phi_{|n|,m} \end{pmatrix}, \quad (36)$$

for the valley K' ($\xi = -1$). Here $C_n = 1$ for $n = 0$ and $C_n = 1/\sqrt{2}$ for $n \neq 0$ and

$$\text{sgn}(n) = \begin{cases} 0 & (n = 0) \\ 1 & (n > 0), \\ -1 & (n < 0) \end{cases} \quad (37)$$

where the positive and negative values of n correspond to the conduction and valence bands, respectively. The corresponding Landau energy spectrum takes the form (Castro Neto et al., 2009; Goerbig, 2011; McClure, 1956)

$$\varepsilon_n = \hbar \omega_B \text{sgn}(n) \sqrt{|n|}, \quad (38)$$

where $\omega_B = \sqrt{2}v_F/\ell_0$.

Summarizing, we can say that there are two types of Landau levels in graphene. The first one corresponds to $n = 0$. In this case the wave function is

$$\Psi_{n=0,m}^K = \begin{pmatrix} 0 \\ \phi_{0,m} \end{pmatrix}. \quad (39)$$

This wave function consists of only the $\phi_{0,m}$ Landau function of a conventional system. The interacting electron system at $n = 0$ graphene Landau level is therefore identical to the interacting electron system in $n = 0$ Landau level of the conventional electron system.

The second class of graphene Landau levels correspond to $n \neq 0$. In this case the wave function is

$$\Psi_{n,m}^K = \frac{1}{\sqrt{2}} \begin{pmatrix} \text{sgn}(n) i^{|n|-1} \phi_{|n|-1,m} \\ i^{|n|} \phi_{|n|,m} \end{pmatrix}. \quad (40)$$

Here the graphene wave function is the mixture of n and $n - 1$ Landau wave functions of a conventional electron system.

For Dirac fermions in graphene, the unique feature of the Landau levels (38) is their square-root dependence on both the magnetic field B and the Landau level index n . This behavior is different from that in conventional semiconductor 2D systems with the parabolic energy dispersion discussed above, where the Landau levels have linear dependence on both the magnetic field and the Landau level index [see Eq. 7]. The Landau level of graphene are shown in Fig. 4 as a function of the magnetic field. Here the positive and negative Landau level indices n correspond to the conduction and valence bands, respectively. These unique properties of the Landau levels of Dirac fermions in graphene result in the unconventional Quantum Hall Effect in graphene with quantum Hall plateaus at filling factors $4(n + \frac{1}{2})$ (Novoselov et al., 2004; Zhang et al., 2005).

Bilayer graphene

The bilayer graphene consists of two coupled graphene monolayers (McCann and Falko, 2006; McCann and Koshino, 2013), which can be in two possible main stackings: (i) AA stacking and (ii) Bernal (AB) stacking, which are shown schematically in Fig. 5.

For bilayer graphene with AA stacking, there is a interlayer coupling between the Landau levels of two layers with the same Landau level indices. This coupling changes the energies of the Landau levels of graphene monolayers, but does not affect the wavefunctions of the layers. Therefore, the bilayer graphene Haldane pseudopotentials, which characterize the electron-electron interaction properties, are completely identical to the corresponding pseudopotentials of monolayer graphene.

Fig. 4 The first few Landau levels of graphene monolayer as a function of perpendicular magnetic field. The Landau levels are labeled with integer index n , where positive and negative n correspond to the conduction and valence bands, respectively. The red and blue lines mark the Landau levels for which the FQHE can be observed.

Fig. 5 (a) Bilayer graphene with AA stacking. Here the interlayer hopping couples sublattice A (B) in the top layer with sublattice A (B) in the bottom layer. (b) Bilayer graphene with AB stacking. For such stacking, sublattice A (B) in the top layer is coupled to sublattice B (A) in the bottom layer.

For bilayer graphene with Bernal (AB) stacking, the interlayer coupling strongly modifies the properties of the Landau level in the system. The corresponding Hamiltonian for valley $\xi = \pm 1$ has the form (McCann and Falko, 2006)

$$\mathcal{H}_{\xi}^{(AB)} = \xi \begin{pmatrix} \frac{U}{2} & v_F \pi_- & 0 & 0 \\ v_F \pi_+ & \frac{U}{2} & \xi \gamma_1 & 0 \\ 0 & \xi \gamma_1 & -\frac{U}{2} & v_F \pi_- \\ 0 & 0 & v_F \pi_+ & -\frac{U}{2} \end{pmatrix}, \quad (41)$$

where U is the inter-layer bias voltage and $\gamma_1 \approx 400$ meV is the interlayer hopping integral. The corresponding wave functions have the structure of $(\psi_{A_1}, \psi_{B_1}, \psi_{A_2}, \psi_{B_2})^T$, where A_1, B_1 correspond to the lower monolayer and A_2, B_2 correspond to the upper monolayer. From the Hamiltonian (41), the Landau level wave functions are

$$\Psi_{n,m}^{(bi)} = \begin{pmatrix} \xi C_1 \phi_{n-1,m} \\ C_2 \phi_{n,m} \\ C_3 \phi_{n,m} \\ \xi C_4 \phi_{n+1,m} \end{pmatrix}, \quad (42)$$

where C_1, C_2, C_3 , and C_4 are constants. The wave functions in the bilayer graphene with AB stacking are therefore the mixtures of the conventional Landau wavefunctions with indices $n-1, n$, and $n+1$.

In Eq. (42) the Landau index n can take the following values: $n = -1, 0, 1, \dots$. Here we assume that if the index of the Landau wave function, $\phi_{n,m}$, is negative then the function is identically zero, which means that $\phi_{-2,m} \equiv 0$ and $\phi_{-1,m} \equiv 0$. Hence, for $n = -1$,

the wave function (42) is just $\Psi_{-1,m}^{(\text{bi})} = (0, 0, 0, \phi_{0,m})$, i.e., the coefficients C_1, C_2, C_3 are zero. Therefore, there is only one energy level corresponding to $n = -1$. For $n = 0$, the wave function (42) has zero coefficient C_1 and, correspondingly, there are only three energy levels.

For $n > 0$, there are four eigenvalues of the Hamiltonian (41), corresponding to four Landau levels in a bilayer graphene at a given valley $\xi = \pm 1$. The eigenvalue equation, which determines the Landau levels is written as (Pereira et al., 2007)

$$[(\varepsilon + \xi u)^2 - 2n] [(\varepsilon - \xi u)^2 - 2(n+1)] = \tilde{\gamma}_1^2 [\varepsilon^2 - u^2], \quad (43)$$

where ε is the energy of the Landau level in units of $\varepsilon_B, \varepsilon_B = \hbar v_F / \ell_0, \tilde{\gamma}_1 = \gamma_1 / \varepsilon_B$, and $u = U / \varepsilon_B$.

The four Landau levels determined by Eq. (43) have two levels with negative energy (valence band) and two levels with positive energy (conduction band). It is then convenient to label these levels as follows: for a given value of n and a given valley ξ we label the levels as $n_i^{(\xi)}$, where $i = -2, -1, 1, 2$ in the ascending order and the negative and positive values of i correspond to the valence and conduction bands, respectively. Although for $n = 0$ there are only three Landau levels and for $n = -1$ there is only one Landau level, it is convenient to combine them in a single set of $n = 0$ Landau levels and label them as $0_i^{(\xi)}$, where $i = -2, -1, 1, 2$. Also, the Landau levels of different valleys are related as follows $\varepsilon(n_i^{(\xi)}) = -\varepsilon(n_{-i}^{(-\xi)})$. A few lowest Landau levels of bilayer graphene are shown in Fig. 6 as a function of the magnetic field.

With the known wave functions (42) of the bilayer graphene Landau levels, the form factor in Eq. (8) for Haldane pseudopotentials can be obtained from the following expression

$$F_n(q) = |C_1|^2 L_{n-1}(q^2/2) + (|C_2|^2 + |C_3|^2) L_n(q^2/2) + |C_4|^2 L_{n+1}(q^2/2). \quad (44)$$

There are two special Landau levels of bilayer graphene with almost zero energy (Apalkov and Chakraborty, 2011), see Fig. 6. The first one corresponds to $n = -1$ with the energy of $\varepsilon = -\xi u$ and the corresponding wave function

$$\Psi_{0_1^{(+)},m}^{(\text{bi})} = \Psi_{0_{-1}^{(-)},m}^{(\text{bi})} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ \phi_{0,m} \end{pmatrix}. \quad (45)$$

The wave function consists of only the $n = 0$ conventional Landau level wave function. Therefore, the FQHE in this bilayer Landau level is exactly the same as the one in the 0-th conventional Landau level. For example, we can say that there is no FQHE in the half-filled $0_1^{(+)}$ Landau level.

In order to find the half-filled level with possible Pfaffian function as the ground state, the most interesting bilayer Landau level is $0_{-1}^{(+)}$ in the K valley and $0_1^{(-)}$ in the K' valley (Apalkov and Chakraborty, 2011). For small values of U , the energy of this state is almost zero, $\varepsilon \approx 0$. The wave function of $0_{-1}^{(+)}$ Landau level has the form

$$\Psi_{0_{-1},m}^{(\text{bi})} = \frac{1}{\sqrt{\sim \gamma_1^2 + 2}} \begin{pmatrix} 0 \\ \sqrt{2} \phi_{0,m} \\ 0 \\ \sim \gamma_1 \phi_{1,m} \end{pmatrix} = \frac{1}{\sqrt{\gamma_1^2 + 2\varepsilon_B^2}} \begin{pmatrix} 0 \\ \sqrt{2\varepsilon_B} \phi_{0,m} \\ 0 \\ \gamma_1 \phi_{1,m} \end{pmatrix}. \quad (46)$$

Fig. 6 A few lowest Landau levels of bilayer graphene as a function of the magnetic field. The bilayer graphene has the AB stacking. The Landau levels of both K and K' are shown. The red lines show special Landau levels, at which the $\nu = 1/2$ Pfaffian incompressible state can be realized. The bias voltage is 5 mV and interlayer hopping integral is $\gamma_1 = 400$ meV.

The wave function is the mixture of $\phi_{0,m}$ and $\phi_{1,m}$ states. For a relatively small magnetic field, $\varepsilon_B \ll \gamma_1$, the wave function becomes $(0, 0, 0, \psi_{1,m})^T$, i.e., it is completely identical to the $n = 1$ conventional Landau level. In a large magnetic field, $\varepsilon_B \gg \gamma_1$, the $0_{-1}^{(+)}$ Landau wave function becomes $(0, 0, \psi_{0,m}, 0)^T$, i.e., it is the same as $n = 0$ conventional Landau level. The interesting aspect of this is that, by varying the magnetic field the electron-electron interactions within the $0_{-1}^{(+)}$ Landau level transform from $n = 1$ to the conventional $n = 0$ case.

Pfaffian states in graphene

Graphene monolayer

The electron-electron interactions and correspondingly the nature of the ground state within a given Landau level are determined by the Haldane pseudopotentials, which are defined by the corresponding form factor $F(q)$. For the graphene monolayer there are two types of Landau levels: (i) the $n = 0$ Landau level and (ii) the $n \neq 0$ levels. For the $n = 0$ Landau level, the form factor is given by

$$F_0(q) = L_0(q^2/2) = 1. \quad (47)$$

This is exactly the same form factor as the one for the $n = 0$ conventional Landau level, for which there is no $\nu = 1/2$ FQHE state. We can then conclude that in the $n = 0$ graphene Landau level, there is no incompressible $\nu = 1/2$ -FQHE state with the Pfaffian function as a ground state wave function. At the same time, all other FQHE states, such as p/q with odd q , have exactly the same properties, i.e., the same ground state wave functions and the same excitation gaps, as the ones for the $n = 0$ conventional Landau level. This suggests that, as long as there is no inter-Landau level mixing, the electron systems in the $n = 0$ graphene Landau level are identical to the systems in the $n = 0$ conventional Landau level.

On the other hand, for the $n \neq 0$ graphene Landau level, the form factor is

$$F_n(q) = \frac{1}{2} (L_{n-1}(q^2/2) + L_n(q^2/2)). \quad (48)$$

For example, for $n = 1$, $L_0(q^2/2) = 1$ and $L_1(q^2/2) = 1 - q^2/4$ and the form factor is $F_1(q) = 1 - q^2/4$. In this case the form factor is the mixture of the form factors of n and $n - 1$ conventional Landau levels. The electron-electron interactions in this case are completely different from those in conventional systems. One of these differences is related to stability, i.e., the magnitude of the excitation gaps of the conventional FQHE with the filling factor p/q , where q is odd. This means that, out of all the graphene Landau levels, including the $n = 0$ Landau level, the largest FQHE gaps are realized in the $n = 1$ Landau level (Apalkov and Chakraborty, 2006; Chakraborty and Apalkov, 2014). This is different from conventional systems, where the conventional FQHE states have the largest gaps for the $n = 0$ Landau level.

Our extensive numerical analyses have established that there is no incompressible $\nu = 1/2$ state of the Pfaffian type for $n = 0$ and $n = 1$ graphene Landau levels (Apalkov and Chakraborty, 2006). Here, the excitation gap is small and the overlap of the ground state wave function with the Pfaffian function is also small. This analysis has been done without considering any inter-Landau level mixing. This mixing can alter the properties of the half-filled Landau level, resulting in the formation of an incompressible state. For example, for conventional systems it was shown that the inter-Landau level mixing favors the anti-Pfaffian state over other type of ground states of the half-filled $n = 1$ Landau level (Rezayi, 2017). Also, both for conventional and graphene systems, the Landau level mixing crucially modifies for the $1/2$ -FQHE state the Haldane pseudopotentials V_1 , V_3 , and V_5 (Peterson and Nayak, 2013). The Landau level mixing is also more pronounced in higher Landau levels. It should be noted that, recent experimental results (Kim et al., 2019) indeed suggest that the incompressible $\nu = 1/2$ state may be realized in monolayer graphene, albeit in higher $n = 3$ Landau level. Here, the inter-Landau level mixing can be important and it can be the reason for the incompressible $\nu = 1/2$ state being present in the higher Landau level in graphene. Further, the even-denominator incompressible states have been observed experimentally in low Landau levels in graphene within some range of the magnetic fields (Zibrov et al., 2018), but the origin of those states is yet to be clearly determined and it can perhaps be related to multicomponent fractional quantum Hall states.

Bilayer graphene

For a Landau level of bilayer graphene, the form factor is given by the expression (44). Due to the bilayer nature of the system, there are extra parameters which can control the form factor and correspondingly the interaction strength. These parameters are the bias voltage and the direction of the magnetic field, i.e., the component of the magnetic field that is parallel to the bilayer. As we have mentioned above, in bilayer graphene there are two 'special' Landau levels $0_{-1}^{(+)}$ (K valley) and $0_1^{(-)}$ (K' valley) for which the Pfaffian function can be the ground state of the half-filled Landau level (Apalkov and Chakraborty, 2011; Chakraborty and Apalkov, 2013).

Extensive studies of the finite-size system of bilayer graphene have been performed by us in the spherical geometry (Apalkov and Chakraborty, 2010, 2011; Chakraborty and Apalkov, 2013, 2014). Those studies have revealed that for all bilayer Landau levels, except the ones $0_{-1}^{(+)}$ and $0_1^{(-)}$, the overlap of the $\nu = \frac{1}{2}$ ground state with the Pfaffian state is relatively small (less than 0.5). Therefore, for those Landau levels, the $\nu = \frac{1}{2}$ system is gapless and compressible. A different situation occurs for the Landau levels $0_{-1}^{(+)}$ and $0_1^{(-)}$. These levels belong to the K and K' valleys, respectively, and have exactly the same interaction properties. Hence, it is enough to consider only one of these levels, e.g., $0_{-1}^{(+)}$, as for the other Landau level, $0_1^{(-)}$, the results are exactly the same.

For the $0_{-1}^{(+)}$ Landau level the form factor is

$$F_{0-1}(q) = \left[\frac{\gamma_1^2}{\gamma_1^2 + 2\varepsilon_B^2} \right] L_1(q^2/2) + \left[\frac{2\varepsilon_B^2}{\gamma_1^2 + 2\varepsilon_B^2} \right] L_0(q^2/2). \quad (49)$$

The strength of the magnetic field is determined by the parameter ε_B . With increasing magnetic field, i.e., with increasing ε_B , the form factor of the $0_{-1}^{(+)}$ level goes through the following main regions: (i) for small B , $\varepsilon_B \ll \gamma_1$, the form factor is $L_1(q^2/2)$ and identical to the one of the $n = 1$ conventional Landau level; (ii) at $\varepsilon_B = \gamma_1/\sqrt{2}$, the form factor is $\frac{1}{2}[L_0(q^2/2) + L_1(q^2/2)]$ and is the same as the one of the $n = 1$ Landau level of monolayer graphene; (iii) at $\varepsilon_B \gg \gamma_1$, the form factor is $L_0(q^2/2)$ and is the same as the one of the $n = 0$ conventional Landau level.

Since the $\nu = 1/2$ incompressible state is realized only in the $n = 1$ conventional Landau level, then for bilayer graphene, the $\nu = 1/2$ Pfaffian state should be observed only for relatively small values of the magnetic field. At the same time, it so happens that as a function of the magnetic field, the characteristics of the $\nu = 1/2$ system is not monotonic. In Fig. 7A the overlap of the $\nu = 1/2$ wave function with the Pfaffian function is shown as a function of the magnetic field. The calculations were done in a spherical geometry for $N_e = 14$ electron system. The overlap has a maximum at a finite magnetic field. The position of the maximum depends on the interlayer hopping integral, γ . For example, for $\gamma = 400$ meV, the maximum overlap occurs for ≈ 10 T. The profile of the overlap is also correlated with the gap of the collective excitation of the system [see Fig. 7B]. The energy gap also has a maximum at a finite magnetic field. Since in a small magnetic field, $B \rightarrow 0$, the $0_{-1}^{(+)}$ bilayer Landau system is equivalent to $n = 1$ conventional Landau systems, we are allowed to conclude that the stability of the Pfaffian $\nu = \frac{1}{2}$ state in bilayer graphene can be increased compared to that of the conventional systems.

The position of the maximum in Fig. 7 can be analyzed further by looking at some dimensionless quantities. For instance, in dimensionless units the maximum is achieved at $\gamma_1/\varepsilon_B \approx 4.9$. This means that, in terms of the magnetic field, the position of the maximum of the overlap is approximately proportional to γ_1 , which is also seen in Fig. 7.

Using the phase diagram shown in Fig. 2, which characterizes the stability of the $\nu = 1/2$ state described by the Pfaffian function, we can illustrate how the interaction parameters in the $0_{-1}^{(+)}$ Landau level change with the magnetic field [see Fig. 8]. For a small magnetic field, the ground state of the system is well described by the Pfaffian function, while the overlap and the corresponding excitation gap reach their maximum at intermediate values of the magnetic field and finally, for a large magnetic field, > 100 T, the electron system becomes compressible.

Another parameter that can be used to control the stability of the Pfaffian ground state, is the magnetic field that is *parallel* to the 2D layer (Chakraborty and Apalkov, 2013). The reason why the parallel magnetic field changes the wave functions and the interaction potential is due to the bilayer nature of the system. In this case the system has extra dynamics in the z direction, which is described in the model as an inter-layer hopping. The parallel component of the magnetic field can be introduced into the Hamiltonian of bilayer graphene through a Peierls substitution as an extra position-dependent phase factor in the inter-layer hopping integral. The details of that study can be found elsewhere (Chakraborty and Apalkov, 2013).

Fig. 7 Panel (A): Overlap of the ground state wave function of $\nu = 1/2$ state with the Pfaffian state as a function of the magnetic field. Panel (B): the collective excitation gap of the $\nu = 1/2$ state as a function of the magnetic field. The data are shown for the Landau level $0_{-1}^{(+)}$ of the bilayer graphene and for two values of the interlayer hopping integral, γ_1 . Reproduced with permission from Apalkov VM, and Chakraborty T (2011) Stable Pfaffian state in bilayer graphene. *Physical Review Letters* 107: 186803, doi:10.1103/PhysRevLett.107.186803.

the perpendicular component of the magnetic field. Therefore, the parallel component of the magnetic field can be used to tune the stability of the Pfaffian state and the magnetic field where it can be realized.

Finding the Pfaffians

Even-denominator fractional quantum Hall effect has been observed experimentally in bilayer graphene (Li et al., 2017; Zibrov et al., 2017). It was found that the corresponding states were spin-polarized and it was suggested that they are Pfaffian or anti-Pfaffian states corresponding to the half-filled Landau level. Such states were observed at high energy bilayer Landau levels that are a mixture of the $n = 1$ and $n = 0$ conventional Landau levels. It was noted that the FQHE was observed only at the filling factor $\nu = 3/2$, but not at $\nu = 1/2$ and $5/2$ (Li et al., 2017). This observation illustrates the high sensitivity of the half-filled incompressible states to the structure of the electron wave functions which determine the electron-electron interaction potentials. Also the measured activation gap of the half-filled incompressible state was several times larger than the largest gaps measured in the GaAs systems (Zibrov et al., 2017), which also illustrates that the half-filled FQHE state is much more stable in bilayer graphene than in conventional electron systems. It was observed that the stability of the experimentally found $1/2$ -FQHE states is sensitive to both the magnitude of the magnetic field and the perpendicular component of the electric field. With variation of these parameters, transitions from the compressible to the incompressible states have been observed (Li et al., 2017). Such a behavior is in complete accord with our theoretical predictions elaborated in the previous section.

Conclusion

Two-dimensional electron systems placed in a strong magnetic field can support charged excitations with fractional charge and non-Abelian statistics. These excitations are possible only due to the nature of electron-electron interactions of a special type. An example of such a system is an electron gas in a given Landau level that is only half filled. Under a special profile of the interaction potential, the ground state of the $\nu = 1/2$ -Landau level is described by the Pfaffian function. Here the profile of interaction potential is determined by the form factor of the corresponding Landau level. As a result, for the conventional electron systems, the incompressible $\nu = 1/2$ -FQHE state is realized only in the $n = 1$ Landau level, but for the graphene monolayer which has the relativistic-like low-energy dispersion (that of the Dirac fermions), there is no incompressible $\nu = 1/2$ Pfaffian state in any Landau level. This theoretical conclusion is based on the properties of electrons within a given Landau level, without considering the admixture of other Landau levels. The Landau level mixing, which is especially relevant for higher Landau levels, can modify the properties of the half-filled Landau states [see Luo and Chakraborty, 2017; Pakrouski et al., 2015; Peterson and Nayak, 2013; Rezayi, 2017; Rezayi and Simon, 2011; Simon and Rezayi, 2013]. It can also open up the possibility to observe the $\nu = 1/2$ -FQHE in higher Landau levels in graphene (Kim et al., 2019).

In this context, bilayer graphene is truly unique because for bilayer graphene with AB stacking, there are two special Landau levels: one in the K valley and another one in the K' valley, for which, there is a range of magnetic fields where the $\nu = 1/2$ ground state is determined by the Pfaffian function. Stability of such a ground state, i.e., its collective excitation gap, depends on the magnetic field and for a finite magnetic field, the $\nu = 1/2$ -FQHE state becomes even more stable than the corresponding state in a conventional electron system. Another important property of bilayer graphene is that there are external parameters, such as the bias voltage and the in-plane magnetic field, that can alter the inter-electron interaction strength within a given Landau level and correspondingly change the properties of the $\nu = 1/2$ Pfaffian state.

In addition to the unique properties of the $\nu = 1/2$ Pfaffian state, the system with half filling of a given Landau level has another interesting feature. In particular, when the projection on a given Landau level is considered, i.e., only the states within this Landau level are taken into account with inter-landau level mixing, then the system itself has a particle-hole symmetry. It means that it can be described either as the $\nu = 1/2$ particle (electron) system or the $\nu = 1/2$ hole system. The Pfaffian function, which describes the $\nu = 1/2$ particle system, is not invariant under the exchange of particles and holes. When the particle-hole symmetry operation is applied to the Pfaffian function it generates the Pfaffian conjugated function, which is known as the anti-Pfaffian (Lee et al., 2007; Levin et al., 2007). The anti-Pfaffian function is given by

$$\Psi_{\text{apf}} = \text{Pf} \left[\frac{z_i - z_j}{(z_i^* - z_j^*)^2} \right] \prod_{i < j} (z_i - z_j)^2 \exp \left(- \sum_i \frac{z_i^2}{4\ell_0^2} \right). \quad (50)$$

In addition to the Pfaffian and anti-Pfaffian functions, another type of function have been proposed in the literature. It is called the PH-Pfaffian and is symmetric with respect to the particle-hole symmetry operator (Son, 2015). The PH-Pfaffian is given by the following expression

$$\Psi_{\text{PH-Pf}} = \text{Pf} \left[\frac{1}{z_i^* - z_j^*} \right] \prod_{i < j} (z_i - z_j)^2 \exp \left(- \sum_i \frac{z_i^2}{4\ell_0^2} \right). \quad (51)$$

All these functions, Pfaffian, anti-Pfaffian, and PH-Pfaffian, are of the superconductor-type with Cooper pairing but having different pairing symmetries. The corresponding charged excitations are non-Abelian anyons. Discussion of the conditions under which

different Pfaffian-type functions are to be realized and their properties can be found in the literature (Antonić et al., 2018; Bonderson et al., 2011; Hsin et al., 2020; Pakrouski et al., 2015; Peterson and Nayak, 2013; Rezayi, 2017; Rezayi et al., 2021; Rezayi and Simon, 2011; Simon and Rezayi, 2013; Sodemann and MacDonald, 2013; Wójs et al., 2010; Zaletel et al., 2015). Confirmation of the presence of Pfaffian functions in half-filled FQHE will provide another open door to our understanding of this distinctive many-body phenomena, the FQHE, guided primarily by the Laughlin function, that have enthralled us for more than four decades. Additionally, it would be equally exciting to watch that the work of Cayley and Pfaff finally see the light of day through bilayer graphene.

Abstract

The fractional quantum Hall effect in 2D electron gases submitted to large magnetic fields remains one of the most striking phenomena in condensed matter physics. Historically, the first observed signature is a Hall resistance quantized to the value $h/(e^2\nu)$ when the filling factor ν (electron density divided by magnetic flux quantum density) of a 2D electron gas is in the vicinity of an inverse odd integer $\nu \approx 1/(2m + 1)$. This was one of the first observation of fractional quantum numbers. A large part of our basic theoretical understanding of this effect (and descendants) originates from Laughlin's theory of 1983, reviewed here from a mathematical physics perspective. We explain in which sense Laughlin's proposed ground and excited states for the system are rigid/incompressible liquids, and why this is crucial for the explanation of the effect.

Key points

- Discuss the basic phenomenology of the fractional quantum Hall effect (FQHE) in 2D electron gases (2DEG).
- Introduce Laughlin's theory of the effect at filling fraction $1/\ell$, ℓ an odd integer.
- Highlight two key incompressibility/rigidity properties the theory relies on.
- Explain the rigorous derivation of Haldane pseudo-potentials (whose ground eigenstates are generated from Laughlin's function) from first principles.
- State the (still open) spectral gap conjecture for said pseudo-potentials (first key rigidity property).
- State incompressibility estimates ensuring that the Laughlin phase is stable against external potentials and residual interactions (second key rigidity property). This essay is partially based on two previous review texts Rougerie (2018, 2022).

Introduction: Phenomenology of the FQHE

Experimental facts

The (fractional) (quantum) Hall effect (Jain, 2007 Girvin, 2004 Goerbig, 2009. Störmer et al., 1999 Laughlin, 1999) concerns the charge transport properties in 2D samples submitted to large magnetic fields. The Lorentz force exerted by the latter on moving charges leads to a non-trivial transverse resistance $R_{xy} = V_y/I_x$ when a current I_x is applied in some direction x . The classical effect has historically served as a way of measuring the charge carriers' density in a given sample. It is however in the 1980's that dramatic, purely quantum signatures were discovered in this context: the quantum Hall effect (integer, then fractional). This led to two Nobel prizes in physics (von Klitzing, 1985, Störmer-Tsui-Laughlin, 1998) and a half (Thouless-Haldane-Kosterlitz, 2016) and the advent of topology as a tool to classify phases in condensed matter physics.

Fig. 1 The fractional quantum Hall effect (Störmer et al., 1999). Sketch of the experimental sample in top-left corner. Plots of the longitudinal $R_{xx} = V_x/I_x$ and transverse (Hall) $R_{xy} = V_y/I_x$ resistances as a function of the magnetic field.

We will limit our discussion to (some of the) most striking experimental findings as depicted on Fig. 1. Namely, consider a 2D gas of electrons submitted to a current and let the filling factor

$$\nu := \frac{hc}{e} \frac{\rho}{B} \quad (1)$$

with ρ the electrons' density, B the applied magnetic field and h , c , e respectively Planck's constant, the speed of light and the elementary charge. Around certain particular values of said factor:

- The direct resistance $R_{xx} = V_x/I_x$ exhibits sudden drops to almost 0 values.
- Simultaneously the Hall/transverse resistance $R_{xy} = V_y/I_x$ is very precisely quantized to the value $h/(e^2\nu)$, which stays stable for a certain window (plateau) of the applied field/filling factor.

Note that the value $h/(e^2\nu)$ taken by R_{xy} is precisely that one can derive from classical considerations. Thus the essence of the quantum effect is the plateau: that the measured resistance sticks on this value for a finite window of ν 's around certain particular values.

The special values of ν at which the above happens are

- integers $\nu = 1, 2, 3, \dots$. This is the integer quantum Hall effect (IQHE).
- certain fractions, in particular $\nu = 1/m$, m odd. This is the fractional quantum Hall effect (FQHE).

The classification of all fractions at which the effect should occur is not a closed topic (as far as I know) but the most prominently observed are of the form

$$\nu = m + \frac{p}{2pn + 1}, \quad m, p, n \text{ integers.} \quad (2)$$

This is certainly the case on Fig. 1, where actually one mostly sees the case $n = 1$. The particular case $p = 1$, n integer corresponds to Laughlin fractions, discussed below. For larger p one gets Jain fractions ($n = 1$, p integer corresponds to the principal Jain sequence, most prominent on the figure), explained in terms of the composite fermions theory (Jain, 2007), a generalization of Laughlin's picture we will not touch upon. Fractions of the form

$$m + 1 - \frac{p}{2pn + 1}$$

correspond to a certain particle-hole transformation of those of the form (2), and their theory is thus the same.

Laughlin's theory and its' composite fermions generalization give a rationale for essentially all the features observed on Fig. 1. The most noteworthy unclear feature lies in the oscillations¹ in R_{xx} around $\nu = m + \frac{1}{2}$, $m = 0, 1$. Those however also have an explanation in terms of the composite fermions theory (Jain, 2007), that we will shall not discuss.

¹Something different occurs at $\nu = 5/2$, see the chapter (Yngvason, 2022) "Quantum Hall states in higher Landau levels" by Jakob Yngvason.

Theoretical road-map

We will in the sequel give a mathematical physics perspective on the above facts, taking for granted the generally accepted hierarchization of energy scales leading to the effect, at least in its purest form:

- (1) The perpendicular magnetic field is so large that the magnetic kinetic energy of electrons is by and large the main player.
- (2) Next comes the repulsive interaction energy of electrons, due to Coulomb forces. The shortrange, singular, part is thought to be the most important.
- (3) Finally all other energies are small compared to the previous ones. In particular, the temperature is neglected altogether. However, the electrostatic potential generated by impurities in the sample is crucial to the effect, and must be taken into account.

The essence of Laughlin's theory is that it provides a tentative ground state/vacuum for the system so that

- The magnetic kinetic energy is minimized exactly.
- The interaction energy is strongly reduced, in particular its' short range part.
- The filling factor is close to $1/m$, m an odd integer. This appears a posteriori after considering the first two points.
- The shape of the ground state is very robust, in particular in its' response to residual interactions and/or external fields.
- The response to external fields is to generate quasi-particles/holes of charge e/m , which serve as effective charge carriers in transport experiments.

The fourth point in particular is the aspect referred to in the title of this essay.

Basic theory

Before going into more precise statements regarding the rigidity/incompressibility of the Laughlin state, we explain its' basic, heuristic, derivation.

The many-body quantum Hamiltonian

We start from a basic Hamiltonian for the quantum 2D electron gas (in neologism form $\hbar = c = e = 2m = 1$)

$$H_N^{\text{QM}} = \sum_{j=1}^N \left[\left(-i\nabla_{\mathbf{x}_j} - \frac{B}{2} \mathbf{x}_j^\perp \right)^2 + V(\mathbf{x}_j) \right] + \sum_{1 \leq i < j \leq N} W(\mathbf{x}_i - \mathbf{x}_j) \quad (3)$$

acting on $L^2_{\text{asym}}(\mathbb{R}^{2N})$, the Hilbert space for N 2D fermionic particles. Here $\mathbf{x}^\perp$ denotes the vector $\mathbf{x} \in \mathbb{R}^2$ rotated by $\pi/2$ counter-clockwise, so that

$$\text{curl} \frac{B}{2} \mathbf{x}^\perp = B$$

and thus $\frac{B}{2} \mathbf{x}^\perp$ is the vector potential of a uniform magnetic field, expressed in symmetric gauge. In view of our choice of units, B is actually $\sqrt{\alpha}$ times the physical magnetic field, with $\alpha = e^2/(\hbar c) \sim 1/137$ the fine structure constant, see e.g. (Lieb and Seiringer, 2010, Section 2.17).

We take into account an external potential $V : \mathbb{R}^2 \mapsto \mathbb{R}$ modeling trapping and/or impurities in the sample, and repulsive pair interactions $W : \mathbb{R}^2 \mapsto \mathbb{R}$ between particles. Typically W should be the 3D Coulomb kernel (with α the fine structure constant again)

$$W(\mathbf{x} - \mathbf{y}) = \frac{\alpha}{|\mathbf{x} - \mathbf{y}|} \quad (4)$$

or some screened version. We have made the customary assumption that the magnetic field is strong enough to polarize all the electrons' spins.

Quantum Hall plateaux

The extremely precise quantization to particular values of R_{xy} (read on the vertical axis of Fig. 1) has an interpretation in terms of topological invariants of the system (Bellissard et al., 1994; Fröhlich, 1992, 1995), but that is not what we focus on here. Instead, looking at the horizontal axis of Fig. 1, we see that the particular features occur around special values (the numbers associated with arrows on the picture) of the filling factor (1) of the system.

In the sequel we (partially) address only the question "why does something special happen at these parameter values?" without touching much on the "how does the particular observed experimental signature emerge?" In a nutshell, the integer values found for R_{xy}^{-1} in the IQHE are Chern numbers associated to the ground state of free electrons in large magnetic fields. The fractional values of the FQHE can roughly be thought of as Chern numbers associated to the ground states of free quasi-particles generated on top of the strongly correlated FQH ground states.

Landau levels

The workhorse of the quantum Hall effect is the quantization of kinetic energy levels in the presence of a magnetic field. Namely, the appropriate kinetic energy operator for a 2D particle in a perpendicular magnetic field B is

$$H = \left(-i\nabla_{\mathbf{x}} - \frac{B}{2}\mathbf{x}^{\perp} \right)^2 \quad (5)$$

acting on $L^2(\mathbb{R}^2)$.

The energy levels (eigenvalues) of the above are well-known (Rougerie and Yngvason, 2020, Jain, 2007) to be $2B(n + 1/2)$ for integer n , since one can write

$$H = 2B \left(a^{\dagger}a + \frac{1}{2} \right)$$

for appropriate ladder operators $a, a^{\dagger}$ with $[a, a^{\dagger}] = 1$. The lowest eigenspace (lowest Landau level, corresponding to the eigenvalue B) can be represented as

$$\text{LLL} = \left\{ f(z) e^{-\frac{B}{4}|z|^2} \in L^2(\mathbb{R}^2), f \text{ holomorphic} \right\} \quad (6)$$

and the n -th Landau level can be obtained as $(a^{\dagger})^n$ LLL. Hence each energy level is infinitely degenerate when working on the full plane. Well-known arguments indicate that this degeneracy is reduced in finite regions, with a degeneracy $\propto B \times \text{Area}$. One argument for this is that (5) can be restricted to a rectangle whose area is a multiple of $2\pi B^{-1}$, imposing magnetic-periodic boundary conditions see (Aftalion and Serfaty, 2007; Almog, 2006; Fournais and Kachmar, 2011; P rice, 2022; Nguyen and Rougerie, 2022) or (Jain, 2007, Sections 3.9 and 3.13). The energy levels are then the same as above, with degeneracy exactly $B(2\pi)^{-1} \times \text{area of the rectangle}$.

The integer quantum Hall effect

Some plateaux (left of Fig. 1) in R_{xy} /drops in R_{xx} occur at integer values of ν and it is not surprising that something special should happen there (again, it is highly non-trivial to derive the specific signature of the “something special”). This can be understood in a non-interacting electrons picture, taking only the Pauli exclusion principle into account. One assumes that the magnetic kinetic energy, proportional to B , is the main player and that all other energy scales in (3) are negligible against it. By this we mean that W is dropped in (3) and that the only effect of V is to essentially confine the gas to a domain Ω .

As the name indicates, the filling factor measures the ratio of electron number to number of available one-body states $N_B(\Omega)$ in a given Landau level (see the above considerations, keeping in mind that $(2\pi)^{-1}h = c = e = 1$):

$$\nu = 2\pi \frac{\rho}{B} = 2\pi \frac{N}{|\Omega|B} \simeq \frac{N}{N_B(\Omega)}$$

if N electrons are confined to the region Ω with density $\rho = N/|\Omega|$. In the ground state of an independent electron picture (taking only the Pauli exclusion principle into account), one fills the eigenstates of (5) with one electron each, starting from the lowest one. At integer ν , the ν lowest Landau levels are thus completely filled, and the others completely empty, a very rigid and nondegenerate situation. This rigidity is actually important in order to treat the energy scales other than B perturbatively.

The fractional quantum Hall effect

Many plateaux however occur at particular *rational* filling factors and are impossible to explain in an independent electrons picture. Laughlin's groundbreaking theory (Laughlin, 1983, 1987, 1999) explains why something special ought to occur at

$$\nu = \frac{1}{\ell}, \ell \text{ an odd integer} \quad (7)$$

e.g. at the right-most plateau $\nu = 1/3$ of Fig. 1, but also at $\nu = 1/5$, a fraction also observed in experiments ($\nu = 1/9$ and lower is not observed, while $\nu = 1/7$ is borderline). The $\nu = 1/3$ fraction is the first to have been observed (Tsui et al., 1982), and the most stable. There are other, more exotic, fractions and features, but let us not get into that to focus on Laughlin's theory of the mother of all fractions, namely (7).

Restriction to the lowest Landau level

We henceforth restrict to filling factors $\nu < 1$. In the regime relevant to the quantum Hall effect, the gap B between the magnetic kinetic energy levels is so large that the first approximation we make is to project all the physics down to as few Landau levels as possible. With filling ratio $\nu \leq 1$, the lowest Landau level is vast enough (again, see the above heuristics) to accommodate all particles, and thus we restrict available many-body wave-functions to those made entirely of lowest Landau² levels orbitals (6). It is in fact convenient to work on the full space at first. The restrictions to finite area/density will actually be performed later, and we will have to make sure they are coherent with our aim: a thermodynamically large system with density $\rho \sim B\nu(2\pi)^{-1}$.

²Generalizations to larger filling factors, when one works in an excited Landau level, are discussed in (Rougerie and Yngvason, 2020).

Killing the interaction's singularity

The main energy scale, the magnetic kinetic energy, is now frozen by projecting all one-body states to (6). Laughlin's key idea is that the next energy scale to be considered is the pair interaction, and more precisely its singular short-range part. Any tentative ground state ought to belong to

$$\text{LLL}_N = \left\{ A(z_1, \dots, z_N) e^{-\frac{B}{4} \sum_{j=1}^N |z_j|^2}, \quad A \text{ analytic and antisymmetric} \right\} \quad (8)$$

and, for ℓ odd, the wave-function

$$\Psi_{\text{Lau}}^{(\ell)}(z_1, \dots, z_N) := c_{\text{Lau}} \prod_{1 \leq i < j \leq N} (z_i - z_j)^\ell e^{-\frac{B}{4} \sum_{j=1}^N |z_j|^2} \quad (9)$$

is introduced in order to reduce as much as possible the probability of particle encounters. $\Psi_{\text{Lau}}^{(\ell)}$ is designed to vanish when $z_i = z_j$ while preserving the anti-symmetry and analyticity. It may seem that ℓ is a free variational parameter. But so far we thought somewhat grand-canonically: we have not fixed the density of our system yet. It turns out that the one-particle density of Laughlin's function satisfies

$$\rho_{\Psi_{\text{Lau}}}(\mathbf{x}) \simeq \frac{B}{2\pi\ell} \mathbb{1}_{|\mathbf{x}| \leq \sqrt{\frac{2N\ell}{B}}}. \quad (10)$$

That is, it lives on a thermodynamically large length scale (whose disk shape shall not bother us to determine bulk properties) and has filling factor $\nu = \ell^{-1}$ (recall the choice of units in (3)). This can be proved rigorously, see e.g. (Rougerie et al., 2013, 2014) and references therein. A common hand-waving heuristic is that in the construction of $\Psi_{\text{Lau}}^{(\ell)}$, one needs ℓ N single particle orbitals

$$\varphi_k(z) = z^k e^{-\frac{B}{4}|z|^2}.$$

Hence the ratio of particle number to available states discussed above should indeed be ℓ^{-1} . One can also derive (Bernevig and Haldane, 2008) that the occupation number of each orbital is $\sim \ell^{-1}$.

Now we can answer our original question “what is special about filling factor $\nu = \ell^{-1}$?” The answer is that, at such parameter values, we may form a Laughlin state of exponent ℓ as approximate ground state of our system. It minimizes the magnetic kinetic energy exactly, and does a very good job at reducing the short-range part of the interaction.

Laughlin quasi-holes

So far we have argued that Laughlin's function is a good ansatz for the ground state of the system at the relevant filling factor, when neglecting the effect of the external potential V and the long-range part of the interaction W in (3). That is not the end of the story, for the latter ingredients do exist in actual experiments, in particular, the disorder landscape that impurities enforce in V is crucial to the quantum Hall effect. It leads to the finite width of the plateau by localizing charge carriers generated when the filling factor varies in the vicinity of a stable (incompressible) fraction (Laughlin, 1981).

The Laughlin state should in fact be seen as the “vacuum” of a theory explaining the FQHE experimental data. The next step is to construct the quasi-particles generated from said vacuum when suitably moderate external fields are applied, such as those generating the currents in experiments.

It is in fact easier to argue about quasi-holes, generated e.g. when the filling factor is lowered a little from the magic fraction ℓ^{-1} , as when moving toward the right on Fig. 1. The salient feature is that we stay on the same FQHE plateau for a while when doing so. It must hence be that the ground state of the system stays “Laughlin-like” for reasonably smaller ν . In fact, Laughlin's next key idea is two-fold:

- for smaller filling factors, the ground state is generated from (9) by adding uncorrelated quasi-holes. These are typically pinned by the impurities of the sample (modeled by V in (3)).
- when applying an external field at ν close to ℓ^{-1} , the current is carried by the motion of such quasi-holes.

The second idea in particular is quite far-reaching: it has by now been measured (Saminadayar et al., 1997; Martin et al., 2004; de Picciotto et al., 1997) that the current is carried in fractional lumps of $e\ell^{-1}$ and (Bartolomei et al., 2020; Nakamura et al., 2020) that the charge carriers obey fractional quantum statistics, i.e. are emergent anyons (Arovas et al., 1984; Halperin, 1984; Lundholm and Rougerie, 2016; Lambert et al., 2022; Zhang et al., 2014; Cooper and Simon, 2015).

To give a bit more mathematical flesh to these heuristics, observe that our considerations above (minimization of the magnetic kinetic energy, almost minimization of the interaction energy) generally suggest to look for states of the form

$$\Psi_F(z_1, \dots, z_N) := c_F \Psi_{\text{Lau}}^{(\ell)}(z_1, \dots, z_N) F(z_1, \dots, z_N) \quad (11)$$

with F analytic and symmetric, c_F a L^2 -normalization constant. The next key steps has a “why go for complications if we can try something simple first” flavor. Namely we consider only a subset of the above possible states, those of the form

$$\Psi_f(z_1, \dots, z_N) := c_f \Psi_{\text{Lau}}^{(\ell)}(z_1, \dots, z_N) \prod_{j=1}^N f(z_j) \quad (12)$$

where $f: \mathbb{C} \mapsto \mathbb{C}$ is analytic and c_f is a normalization constant. In some sense, we try not to add extra correlations on top of the already strongly correlated $\Psi_{\text{Lau}}^{(\ell)}$.

It turns out that states of the form (12) give sufficient freedom to explain the effect. Namely, since f is essentially a polynomial, we write it in the manner

$$f(z) = \prod_{k=1}^K (z - a_k) \quad (13)$$

for points $a_1, \dots, a_K \in \mathbb{C}$. Since Ψ_f must vanish whenever any of the electrons coordinates approaches some $a_{k'}$, those are interpreted as the (here, classical) locations of quasi-holes, whose role in the effect we discussed above.

Stability of the Laughlin phase

In the next section we discuss what is known/hoped for at a mathematical physics level of precision regarding two assumptions implicitly made above:

- The space of functions of the form (11) is indeed an approximate ground eigenspace for (at least the singular part of the) the interaction energy. It is separated from the rest of the spectrum by an energy gap, so that remaining energy scales can be treated perturbatively.
- When minimizing the remaining energy scales in the space (11) (in the spirit of degenerate perturbation theory), it is legitimate to restrict to the simpler form (12) of Laughlin plus quasi-holes wave-functions.

These two aspects are manifestations of the Laughlin state's rigidity/incompressibility. In fact the first one is most often referred to as incompressibility, so that we will refer to the second one as rigidity.

Mathematical results and conjectures

We now discuss in more mathematical details the two questions we mentioned last: (i) that the space (11) constructed from Laughlin's function almost minimizes the interaction energy, (ii) that the subset of Laughlin-plus-quasi-holes functions (12) is a stable subset of (11).

Haldane pseudo-potentials

In the case of true interactions, e.g. Coulombic (4), the Laughlin function is a good guess, but there is no obvious way of justifying this in a well-defined/controlled limit/approximation. However, the question can be given a clear mathematical meaning modulo simplifying the true interaction.

Namely, consider a toy Hamiltonian defined as follows. Let the fermionic lowest Landau level be

$$\text{LLL}_{\text{asym}}^N = \left\{ A(z_1, \dots, z_N) e^{-\frac{\beta}{4} \sum_{j=1}^N |z_j|^2}, \quad A \text{ analytic and antisymmetric} \right\} \quad (14)$$

where antisymmetric means "under exchange of the labels of the coordinates $z_1, \dots, z_N$." On this space, consider the action of the m -th Haldane pseudo-potential Hamiltonian

$$H(m, N) := \sum_{1 \leq i < j \leq N} |\varphi_m\rangle \langle \varphi_m|_{ij} \quad (15)$$

where $|\varphi_m\rangle \langle \varphi_m|_{ij}$ projects the relative coordinate³ $\mathbf{x}_i - \mathbf{x}_j$ of particles i and j on the one-body state (c_m is a normalization constant)

$$\varphi_m(z) = c_m z^m e^{-\frac{\beta}{4}|z|^2}.$$

Note that, when acting on $\text{LLL}_{\text{asym}}^N$, only for odd m does $H(m, N)$ act non-trivially.

To motivate the above definition, we recall that the magnetic kinetic energy is the main energy scale, with discrete energy levels separated by huge gaps. Perturbation theory tells us that we should look for the ground state of the system by minimizing, in the ground eigenspace $\text{LLL}_{\text{asym}}^N$, the next main energy scale, namely the interaction. If one projects a bona-fide pair interaction Hamiltonian

³We identify points in the plane with complex numbers.

$$H_w = \sum_{1 \leq i < j \leq N} w(x_i - x_j)$$

with *radial* potential $w \geq 0$ on the LLL, one obtains

$$H_w^{\text{LLL}} := P_{\text{LLL}_{\text{sym/asym}}^N} H_w P_{\text{LLL}_{\text{sym/asym}}^N} = \sum_{i < j} \sum_{m \geq 0} \langle \varphi_m | w | \varphi_m \rangle \langle \varphi_m |_{ij}. \quad (16)$$

The coefficients $\langle \varphi_m | w | \varphi_m \rangle$ are called “Haldane pseudo-potentials” (Haldane, 1983; Bertsch and Papenbrock, 1999; Rougerie et al., 2014; Lieb et al., 2009; Lewin and Seiringer, 2009; Papenbrock and Bertsch, 2001; Girvin and Jach, 1984; Viefers, 2008). The toy Hamiltonian (15) above is obtained by discarding all terms from the sum but one, in order for the Laughlin state to be an exact ground state, and not just a very good approximation. Indeed, $\Psi_{\text{Lau}}^{(\ell)}$ is clearly an exact ground state

$$H(\ell-2, N) \Psi_{\text{Lau}}^{(\ell)} = 0.$$

The rigorous justification of the expansion in Haldane pseudo-potentials and the truncation of the series is considered in (Lewin and Seiringer, 2009; Seiringer and Yngvason, 2020) (with techniques whose inspiration goes to back to (Dyson, 1957), see (Lieb et al., 2005; Rougerie, 2020)) in the limit of strong short-ranged potentials. One must be careful that for such singular potentials, the Haldane pseudo-potentials have to be modified to account for short-range correlations due to usual two-body scattering. This involves states outside the lowest Landau level.

Let $a > 0$ be a (small) length and (note that we subtract the LLL ground state energy for convenience)

$$H_a := \sum_{j=1}^N \left(\left(-i \nabla_{\mathbf{x}_j} - \frac{B}{2} \mathbf{x}_j^\perp \right)^2 - B \right) + \sum_{1 \leq j < k \leq N} v_a(\mathbf{x}_j - \mathbf{x}_k) \quad (17)$$

where the potential

$$v_a(\mathbf{x}) = a^{-2} v(a^{-1} \mathbf{x}) \quad (18)$$

is scaled to be strong and short-range in the limit $a \rightarrow 0$. The convention is that the integral of v_a is fixed, so that the potential converges to a Dirac delta function. The following is proved in (Seiringer and Yngvason, 2020) (to which we refer for more comments):

Theorem 1: Derivation of Haldane pseudo-potentials.

Let ℓ be an odd number and the scattering coefficient

$$b_\ell := \frac{1}{4\pi\ell} \min \left\{ \int_{\mathbb{R}^2} |\mathbf{x}|^{2\ell} \left(|\nabla f(\mathbf{x})|^2 + \frac{1}{2} v(\mathbf{x}) |f(\mathbf{x})|^2 \right) d\mathbf{x}, f(\mathbf{x}) \xrightarrow{|\mathbf{x}| \rightarrow \infty} 1 \right\}.$$

Set

$$c_\ell := 8\pi\ell (\pi 2^{\ell+1} \ell!)^{-1} b_\ell.$$

When $a \rightarrow 0$

$$a^{-2\ell} H_a \rightarrow c_\ell P_{\ell-2, N} H(\ell, N) P_{\ell-2, N}$$

in strong resolvent sense⁴ on $L_{\text{asym}}^2(\mathbb{R}^{2N})$. Here $H(\ell, N)$ is as in (15) and $P_{\ell-2, N}$ projects on the kernel (11) of $H(\ell-2, N)$, with the convention $P_{\ell-2, N} = 1$ for $\ell = 1$.

This says that the ℓ -th Haldane pseudo-potential is obtained at energies of order $a^{2\ell}$ in the limit of a potential of short range a . There is a multi-scale aspect: to reach such energies, one must first cancel the $\ell-2$ first Haldane pseudo-potentials, whence the projection on their kernel. Note that for $\ell = 1$ there is no such lower Haldane pseudo-potential. Hence $a^{-2} H_a$ converges to $H(1, N)$ acting on the whole L_{asym}^N (that one can identify with (11) for $\ell = 1$), with ground state space generated from $\Psi_{\text{Lau}}^{(3)}$ as in (11). Noteworthy, one can identify $H(1, N)$ using derivatives of the delta- interaction potential,

$$H(1, N) = \pi \sum_{i < j} \Delta \delta(z_i - z_j)$$

where $\delta(z_i - z_j)$ acts as evaluation on the diagonal $z_i = z_j$ (which is a perfectly well-defined operation on the very regular LLL wave-functions).

Corollaries of the above result include that if a suitably small trapping term is added to $a^{2\ell} H_a$, its' ground state converges to $\Psi_{\text{Lau}}^{(\ell)}$, see (Lewin and Seiringer, 2009; Seiringer and Yngvason, 2020) for more details.

⁴ $H_n \rightarrow H$ in this sense if $(\mu + H_n)^{-1} \psi \rightarrow (\mu + H)^{-1} \psi$ for any state vector ψ and any $\mu > 0$.

The spectral gap conjecture

Hence, in a well-defined albeit idealized limit, the Laughlin state is a true ground state. However, the dependence on the particle number of the gap above the zero ground state energy is not known. Thus one cannot take the thermodynamic limit at the same time as the short-range limit, while precisely controlling the approximation.

The solution to this problem is an important conjecture. It says that the gap above the eigenvalue 0 does not close in the thermodynamic limit $N \rightarrow \infty$. To formulate this, observe first that $H(\ell - 2, N)$ commutes with the total angular momentum operator

$$\mathcal{L}_N := \sum_{j=1}^N z_j \partial z_j - \bar{z}_j \partial \bar{z}_j, \quad (19)$$

and consider a joint diagonalization of the two operators on $\text{LLI}_{\text{asym}}^N$. The angular momentum of the Laughlin state (9) is

$$\mathcal{L}_N \Psi_{\text{Lau}}^{(\ell)} = \frac{\ell}{2} N(N-1) \Psi_{\text{Lau}}^{(\ell)}.$$

Conjecture 2: Spectral gap conjecture.

Consider the spectral gap of $H_{\ell-2, N}$ on the sector of angular momenta below that of the Laughlin state

$$\sigma(N, \ell) = \inf \left\{ \text{spec} \left(H(\ell-2, N)_{|\mathcal{L}_N \leq \frac{\ell}{2} N(N-1)} \right) \setminus \{0\} \right\}. \quad (20)$$

There exists a constant $c_\ell > 0$, independent of N , such that

$$\sigma(N, \ell) \geq c_\ell > 0.$$

The above is widely believed to be true (and has been advertised by experts) on the grounds that:

1. It is supported by numerical simulations (numerical diagonalizations of the Hamiltonian for small particle numbers, say up to ~ 20 , see for example (Jain, 2007, Viefers, 2008) and references therein).
2. Where it to be false, it would be extremely hard to make sense of the experimental data of the FQHE, obtained for thermodynamically large systems.

It should not actually be necessary to restrict the Hamiltonian to angular momenta below $\ell N(N-1)/2$ to obtain a lower bound to the spectral gap. It is likely that restricting to angular momenta below a larger value (but still of order N^2 when $N \rightarrow \infty$) would suffice. It is conceivable Yang et al., 2001 that the conjecture holds only for moderate values of ℓ .

There are other versions of the conjecture: for particles living on a sphere or a cylinder instead of in the plane, see (Jain, 2007, Sections 3.10 and 3.11) and references therein. The (appropriately modified) conjecture is known to hold (Nachtergaele et al., 2021, 2020; Warzel and Young, 2021a,b) in one such cases: particles confined to a thin torus, a limit in which the problem starts being reminiscent of a 1D quantum spin chain.

Stability of the Laughlin phase

We now take for granted that, in the FQHE regime around $\nu = \ell^{-1}$, leading energy considerations force us to restrict to trial states of the form (11), for they exhaust all the zero-energy eigenstates of the leading Haldane pseudo-potentials. As we discussed above, that is not the end of the story: we now need to justify the further restriction to the simpler states of the form (12).

We thus consider a Hamilton function

$$\mathbb{R}^{2N} \ni (\mathbf{x}_1, \dots, \mathbf{x}_N) \mapsto \sum_{j=1}^N V(\mathbf{x}_j) + \lambda \sum_{1 \leq i < j \leq N} W(\mathbf{x}_i - \mathbf{x}_j) \quad (21)$$

where $V, W : \mathbb{R}^2 \mapsto \mathbb{R}$ are respectively a one-body and a two-body potential and $\lambda \in \mathbb{R}$ is a coupling constant. We shall discuss the following problem

$$E(N, \lambda) = \inf \left\{ \mathcal{E}_{N, \lambda}[\Psi_F] \mid \Psi_F \text{ of the form (3.9), } \int_{\mathbb{R}^{2N}} |\Psi_F|^2 = 1 \right\} \quad (22)$$

where

$$\mathcal{E}_{N, \lambda}[\Psi_F] = \left\langle \Psi_F \left| \sum_{j=1}^N V(x_j) + \lambda \sum_{i < j} W(x_i - x_j) \right| \Psi_F \right\rangle_{L^2}. \quad (23)$$

In the spirit of degenerate perturbation theory (again), what the above means is that we minimize the remaining potential energy within the (approximate) ground eigenspace of the main energy scales. The two parts of the Hamilton function represent

e.g. energies due to impurities in the sample and/or external fields, and the residual, long-range part of the interaction energy that is not killed by restricting to trial states of the form Ψ_F .

As discussed above, it is important in Laughlin's theory that one can further restrict variational states to the simpler form (12). This can be interpreted as the absence of superfluous correlations, and/or the emergence of quasi-holes generated by the action of external fields on the Laughlin "vacuum." To formulate this mathematically, define a restricted infimum by setting

$$e(N, \lambda) = \inf \left\{ \mathcal{E}_{N,\lambda}[\Psi_f] \mid \Psi_f \text{ of the form (3.10), } \int_{\mathbb{R}^{2N}} |\Psi_f|^2 = 1 \right\}. \quad (24)$$

Obviously $E(N, \lambda) \leq e(N, \lambda)$. What we would like to prove is that there is equality in the thermodynamic limit:

$$E(N, \lambda) \simeq e(N, \lambda) \quad \text{as } N \rightarrow \infty \text{ with } \lambda \text{ fixed.} \quad (25)$$

We now set the (presumably non-optimal, but illustrative) assumptions under which the above has been proved in (Lieb et al., 2018; Lieb et al., 2019; Rougerie and Yngvason, 2018; Olgiati and Rougerie, 2020). Since functions from our variational space (11) naturally live over thermodynamically large length scales $\sim \sqrt{N}$ it is natural to scale the potentials V and W accordingly. We thus set, for fixed functions v, w ,

$$V(x) = v(N^{-1/2}x) \quad (26)$$

and (the N^{-1} pre-factor ensures that the potential and interaction energies stay of the same order when $N \rightarrow \infty$)

$$W(x) = N^{-1}w(N^{-1/2}x). \quad (27)$$

Theorem 3: Energy of the Laughlin phase.

Assume that v and w are smooth fixed functions. Assume that v goes to $+\infty$ polynomially at infinity, and that it has finitely many non-degenerate critical points. There exists $\lambda_0 > 0$ such that

$$\frac{E(N, \lambda)}{e(N, \lambda)} \xrightarrow{N \rightarrow \infty} 1$$

with $B > 0$ fixed, $\ell > 0$ a fixed integer and $|\lambda| \leq \lambda_0$.

In scaling the external potential as in (26) we make it live on the natural, thermodynamically large, length-scale of the Laughlin function. This is very reasonable for the trapping part of the potential, but much less so for the part modeling disorder, which typically lives on a much shorter length scale. We can in fact allow shorter length scales, but improving this to realistic values⁵ remains an open problem. We prefer to use a single length scale, in order not to obscure the statement.

In Theorem 3 we assume the interaction to be smooth. This is because it is supposed to represent the long-range part only, the singular short-range part being taken care of by restricting to (11). Scaling W as in (27) has the merit of making the two terms in (23) of the same order of magnitude, as in a mean-field limit. This also simplifies statements a lot, but for interactions scaling like 3D Coulomb, this is actually the correct thing to do, see (Olgiati and Rougerie, 2020, Section 2.2).

Concerning the smallness assumption on λ in Theorem 3, it corresponds to the fact that the filling factor should stay close to ℓ^{-1} for the theorem to be true. Too large a deviation makes the system jump to a different FQHE plateau, e.g. a Laughlin state with higher exponent. Increasing the (repulsive) interaction strength has the net effect of spreading the system further, and hence lowering the filling factor (see again (Olgiati and Rougerie, 2020, Section 2.2) for more details). An upper bound, probably model-dependent and hard to estimate, on $|\lambda|$ is thus necessary for the statement to hold.

Incompressibility estimates

We will not go into the details of the proof of Theorem 3 (which also has corollaries regarding the optimal densities). We only mention that it mostly relies on a remarkable rigidity property shared by all states of the form (11). We coined this an "incompressibility estimate" in (Rougerie et al., 2014; Rougerie and Yngvason, 2015a, b) where partial results were obtained before the full result below was proved in (Lieb et al., 2019) and improved in (Olgiati and Rougerie, 2020). This notion of incompressibility should not be confused with that discussed in Section 4.1, that it complements (and of which it is logically independent).

Let

$$\varrho_{\Psi_F}(\mathbf{x}) := N \int_{\mathbb{R}^{2(N-1)}} |\Psi_F(\mathbf{x}, \mathbf{x}_2, \dots, \mathbf{x}_N)|^2 d\mathbf{x}_2 \dots d\mathbf{x}_N \quad (28)$$

be the one-particle density associated to Ψ_F of the form (11). We have the universal bound.

⁵The optimal assumption should be that the length scale be much larger than the magnetic length $B^{-1/2}$.

Theorem 4: Incompressibility estimate.

For any $\alpha > (\sqrt{5}-1)/4$, any disk D of radius N^α and any (sequence of) states Ψ_F of the form (11) we have

$$\int_D \varrho_{\Psi_F} \leq \frac{B}{2\pi\ell} |D| (1 + o(1)) \quad (29)$$

where $|D|$ is the area of the disk and $o(1)$ tends to zero as $N \rightarrow \infty$.

What this says is that, in the sense of averages on sufficiently large length scales (which are allowed to be much smaller than the thermodynamic length scale $\sim \sqrt{N}$) and independently of F

$$\varrho_{\Psi_F} \lesssim \frac{B}{2\pi\ell}.$$

I.e. the local filling factor can, in states of the form (11), nowhere be larger than the global filling factor of the Laughlin state.

We conjecture that the result only requires $N^\alpha \gg B^{-1/2}$ (i.e. that the bound holds in the sense of averages on any length scale larger than the magnetic length), but this remains an open problem. Its' solution would go a long way toward removing assumptions on length scales made in Theorem 3.

The proof of the above is based on Laughlin's plasma analogy, which maps the N -particle density of Ψ_F to Gibbs states of fictitious classical 2D electrostatic systems (somewhat contrived for non trivial F). Screening considerations valid in a large generality for these systems yield the result. The form of F can a priori be quite wild, but, being analytic, it leads to a repulsive electrostatic force in the plasma analogy. This can only lower the density compared to the case with no F . Most of the difficulties lie in vindicating this intuitive (but specific to Coulomb interactions) fact. One needs to show it for essentially any form of the corresponding charge distribution, which can be quite bizarre and correlated for general F .

Conclusion

We gave a very rough sketch of Laughlin's theory, the most basic building block of our theoretical understanding of the fractional quantum Hall effect. We argued that two crucial properties, assumed in the general theory, play a key role in making it an efficient description. From a mathematical physics point of view, the first property ("incompressibility") rests on Haldane pseudo-potentials and an open problem concerning their spectra, the spectral gap conjecture (partial results were however obtained recently (Nachtergaele et al., 2021; Nachtergaele et al., 2020; Warzel and Young, 2021a, b)). The second property ("rigidity") can be given the form of a stability question for Laughlin quasi-holes generated from the vacuum of the theory. This has been solved in some generality recently, although important questions remain on the optimal assumptions allowed in the current state of affairs. We did not mention at all extensions of the above considerations to other quantum Hall fractions than the inverse odd integers, simply because this remains a wide open problem.

Acknowledgments

Abstract

We describe here the basic idea of fractional statistics in low dimensions. In quantum mechanics, multiplication of the wave function by a complex phase factor does not change the physical state described by the wave function. Another such physical identity transformation is a permutation of arguments in the wave function if they refer to identical particles. In three dimensions, a swapping of arguments gives rise to a phase factor of + 1 for two bosons and – 1 for two fermions. In two dimensions, fractional statistics appears as a possibility, where an interchange of two particles via a continuous path in the configuration space may give rise to a more general phase factor of $e^{\pm i\theta}$, with the sign of the phase depending on the direction of the path. In one dimension, two particles can be interchanged only by passing through each other. This introduces boundary conditions on the wave functions that may lead to other kinds of fractional statistics. Physical applications of these ideas are only briefly touched upon.

Key points

- Permutation of identical particles does not change the state of a physical system.
- This allows the identical particles to be bosons or fermions.
- A more careful analysis leads one to consider continuous interchange of particles instead of discrete permutations.
- In two dimensions this allows for anyons: particles with statistics between bosonic and fermionic.
- Anyons are observed as quasiparticles in the fractional quantum Hall effect.
- In one dimension the particle statistics appears as a boundary condition on the wave functions.
- The general boundary condition contains a parameter that may interpolate continuously between bosons and fermions.

Introduction

Quantum mechanics gives a unique characterization of both elementary and composite particles as being either *bosons* or *fermions*. This division into two types of particles follows from a simple symmetry argument. As was first noted by Heisenberg and Dirac, when a physical system consists of identical particles it means, by definition, that every observable is symmetric under permutations of the particles. Since symmetric operators preserve the symmetry or antisymmetry of the wave functions, it is possible to have two different quantum theories where the wave functions are restricted to be either symmetric or antisymmetric under permutation of particle coordinates. For two spinless particles, this symmetry is expressed through a sign factor which is associated with the swap of their positions,

$$\psi(\mathbf{r}_1, \mathbf{r}_2) = \pm \psi(\mathbf{r}_2, \mathbf{r}_1), \quad (1)$$

with + for bosons and – for fermions. From the symmetry constraint, when applied to a many-particle system, the statistical distributions of (noninteracting) particles over single particle states can be derived, and the completely different collective behavior of systems like electrons (fermions) and photons (bosons) can be understood.

The restriction to two possible kinds of quantum statistics, represented by the sign factor in (1), may seem almost obvious. On the one hand, the permutation of particle coordinates has no physical significance when the particles are identical, which means that the wave function can change at most by a complex phase factor $e^{i\theta}$. On the other hand, a double permutation seems to make no change at all, which further restricts the phase factor to be either + 1 or – 1. This is a standard argument used in textbooks like (Landau and Lifshitz, 1977).

However, there is little substance in this argument, as pointed out in Leinaas and Myrheim (1977), since the concept of particle interchange is not very precisely defined. We argued that the interchange should be defined as a continuous process rather than a discrete permutation. As a byproduct of this argument, it follows that if the dimension of space is reduced from three to two, the constraint on the phase factor is lifted and a continuum of possibilities appears that interpolates between the boson and fermion

cases. In Leinaas and Myrheim (1977) these unconventional types of quantum statistics, often referred to as fractional statistics, were found by analysis of the wave functions defined on the many-particle configuration space. Other approaches by Goldin et al. (1981) and by Wilczek (1982a, b) lead to similar results, and Wilczek introduced the name *anyon* for these new types of particles.

The discovery of the fractional quantum Hall effect in 1982 gave a boost to the interest in anyons, and many new ideas for the application of the theory have followed. Recent experiments, with a direct observation of fractional statistics in the fractional quantum Hall effect, have also contributed to the continuing interest for this field of quantum physics. Our intention with the present contribution to the Encyclopedia is to discuss the basics of how fractional statistics has appeared as a possibility in two- and one-dimensional many-particle systems, while the interesting ideas of applications of anyons are only briefly commented on.

Fractional statistics in 2D

The difference between the two-dimensional and the three-dimensional cases is illustrated in Fig. 1, where, in two cases, the swapping of positions of two indistinguishable particles is shown as a continuous change of the particle positions in the plane. The curve drawn defines a continuous path in the configuration space, to be thought of as a mathematical object which does not represent a physical process. Assuming that the wave function is nowhere zero along the path, one may follow the continuous change of phase of the wave function. In the case of charged particles in a magnetic field there is a contribution to the phase from the electromagnetic vector potential; this is irrelevant here and should be subtracted.

Since the interchange of identical particles does not change the physical state, all that can happen is that the wave function as a whole will acquire a phase factor of $e^{i\theta}$, where $\theta \pmod{2\pi}$ is a real phase that is characteristic of a given species of particles. The superposition principle requires that the phase factor is the same for all wave functions. It is a reasonable assumption that θ does not change if the path is continuously deformed. Thus we must have $e^{i\theta} = 1$ for every path that can be continuously contracted to a point. An important point here is that we exclude singular points where two particles sit at the same point (these will often be singular points of the wave functions).

In two dimensions, the paths come with an orientation, and as a consequence, the counterclockwise and the clockwise paths are associated with phase factors $e^{i\theta}$ and $e^{-i\theta}$, which in principle may take any values on the complex unit circle. However, if a third dimension is introduced, counterclockwise and clockwise paths can be rotated into each other by use of the third dimension, implying that $e^{i\theta} = e^{-i\theta} = \pm 1$. In two dimensions this opens up for a continuum of intermediate statistics, while in three dimensions there are only two possibilities, bosons and fermions, as expressed in Eq. (1).

The condition on the wave function given in Eq. (1) is one way to express the indistinguishability of the particles in the quantum theory. It is needed because the mathematical points $(\mathbf{r}_1, \mathbf{r}_2)$ and $(\mathbf{r}_2, \mathbf{r}_1)$ represent the same physical situation. However, this double representation of the physics can be eliminated on the classical level, before quantization, thereby giving a new meaning to Eq. (1).

That is easy to demonstrate in the case of two particles in two dimensions. In Fig. 2A the four-dimensional configuration space is reduced to a two-dimensional flat space by removing the center of mass of the two particles. The coordinates of this two-dimensional plane then describe the relative position $\mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2$, and due to the indistinguishability of the particles at $\mathbf{r}_1$ and $\mathbf{r}_2$, the full plane can be reduced to the half-plane, as shown in the figure. Furthermore, since pairs of points along the cut are identical, the full half-plane can be identified as a cone.

The different types of closed curves are determined by the number n of windings around the apex of the cone, where n can take both positive and negative integer values. In Fig. 2B two examples are shown. The first one has winding number $n = 0$, which means that it does not surround the apex, while the second one has winding number $n = 1$. In the quantum description the apex is a singular point of the wave functions, which usually are assumed to vanish at the apex. A wave function will thus under rotation around the apex pick up the phase factor $e^{in\theta}$, where n is the number of windings.

To illustrate this we consider the result for a two-particle case, earlier discussed in Leinaas and Myrheim (1977). The center of mass coordinate is neglected, for the reason already discussed, and the free-particle Hamiltonian is written as

$$H = -\frac{\hbar^2}{m} \left(\frac{\partial^2}{\partial r^2} + \frac{1}{r} \frac{\partial}{\partial r} + \frac{4}{r^2} \frac{\partial^2}{\partial \phi^2} \right), \quad (2)$$

where (r, ϕ) are the polar coordinates in relative space, defined such that

$$x = r \cos(\phi/2), \quad y = r \sin(\phi/2). \quad (3)$$

Fig. 1 Interchanging positions of pairs of indistinguishable particles in two dimensions. The difference between counterclockwise and clockwise interchange gives rise to quantum phase factors $e^{i\theta}$ and $e^{-i\theta}$ in the two cases, where $\theta \pmod{2\pi}$ can take any value between 0 and 2π (or equivalently between $-\pi$ and π). From Leinaas JM (2009) Anyons. In: Greenberger D, Hentschel K, and Weinert F (eds.) *Compendium of Quantum Physics*. Springer-Verlag Berlin Heidelberg, p. 10.

Fig. 2 The relative space of two identical particles in two dimensions. The relative position $\mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2$ is physically identical to $-\mathbf{r} = \mathbf{r}_2 - \mathbf{r}_1$. To avoid this double counting, half the space in (A) can be removed, and identical points on the edge (such as the two points A) can be “glued” together. The result is the cone shown in (B). In (B) there are two circles, where C_1 does not enclose the apex of the cone, and C_2 which does so. In (A) the curve C_1 can be interpreted as change of positions that does not mix $\mathbf{r}_1$ and $\mathbf{r}_2$, while C_2 corresponds to a closed curve where $\mathbf{r}_1$ and $\mathbf{r}_2$ change positions.

Add to this Hamiltonian a harmonic oscillator potential

$$V(\mathbf{r}) = \frac{1}{4} m \omega^2 \mathbf{r}^2. \quad (4)$$

The eigenfunctions of the Hamiltonian, with V added, are written as

$$\psi(r, \phi) = \exp \left[i \left(l + \frac{\theta}{2\pi} \right) \phi \right] R(r), \quad l = 0, \pm 1, \pm 2, \dots \quad (5)$$

In this approach, the statistics phase θ appears explicitly in the wave function, but not in the Hamiltonian. Increasing the angle ϕ by 2π produces an anticlockwise interchange of the particles, and this operation multiplies the wave function by $e^{i\theta}$. Thus the wave functions are single-valued on the cone in Fig. 2 only if the particles are bosons, with $e^{i\theta} = 1$. In the fermion case in particular, with $e^{i\theta} = -1$, the wave functions are double-valued.

It is possible to remove θ from the wave function, by a gauge transformation which introduces a vector potential proportional to θ , but we do not discuss this here.

The radial function $R(r)$ is then determined by the equation

$$\left(\frac{d^2}{dr^2} + \frac{1}{r} \frac{d}{dr} - \frac{4}{r^2} \left(l + \frac{\theta}{2\pi} \right)^2 - \frac{1}{4} \frac{m^2 \omega^2}{\hbar^2} r^2 + \frac{mE}{\hbar^2} \right) R = 0. \quad (6)$$

Except for the presence of θ this has the same form as the radial equation of the harmonic oscillator in two dimensions. With the solutions being nonsingular at the origin, the allowed energies are

$$E = 2\hbar\omega \left(n + \left| l + \frac{\theta}{2\pi} \right| + \frac{1}{2} \right), \quad n = 0, 1, 2, \dots \quad (7)$$

Fig. 3 shows how the energy spectrum changes from that of bosons to that of fermions when the parameter θ changes from 0 to π .

For two anyons in a harmonic oscillator well, the Schrödinger equation is exactly solvable for any value of the anyon variable θ . For more than two particles, however, that is not the case, and the relative configuration space is more complicated than the cone in Fig. 2B. However, if the continuous interchange of the particles is shown as a set of curves in the plane depending on a common time parameter, as in Fig. 4, this defines a pattern known as a braid. The total set of points is the same at the initial time and the final time, but at intermediate times the particle lines may intertwine. The set of all such braids with a given set of endpoints define a *braid group*. Each braid induces a phase factor $e^{in\theta}$ multiplying the anyon wave functions, where n is the total winding number of the braid. For bosons, $\theta = 0$, these phase factors define the trivial representation of the braid group, whereas for fermions, $\theta = \pi$, they define a representation of the braid group which is the antisymmetric representation of the symmetric group S_N . For this reason the fractional statistics, characterized by a more general value of the parameter θ , is often referred to as braiding statistics.

Fractional statistics in 1D

In one space dimension the identification of points in the relative space of two identical particles is

$$x = x_1 - x_2 \equiv -x \quad (8)$$

Fig. 3 The energy spectrum of a two-particle system, in two dimensions, with a harmonic-oscillator interaction, is here shown for three particular values of the parameter θ . The value $\theta = 0$ corresponds to the boson case and $\theta = \pi$ to the fermion case. The degeneracy of each energy level is given in the figure. As the figure indicates, the change of θ gives rise to a continuous transition from the boson to the fermion spectrum. From Leinaas JM and Myrheim J (1977) On the theory of identical particles. *Il Nuovo Cimento* 37: 1.

Fig. 4 When many particles interchange positions, the collection of continuous particle paths can be viewed as forming a braid, and the associated phase factor can be viewed as representing an element of the braid group. From Leinaas JM (2009) Anyons. In: Greenberger D, Hentschel K, and Weinert F (eds.) *Compendium of Quantum Physics*. Springer-Verlag Berlin Heidelberg, p. 10.

and it changes the full line to a half line. The singular configuration $x = 0$, which corresponds to the two particles located at the same position, is now a boundary point of the space. This is unique for one dimension, where two particles cannot interchange positions without actually passing through each other. For this reason the interchange operation is rather different here than in higher dimensions.

Since the singularity now has character of a boundary, it seems natural to represent the effect of the singularity by a boundary condition. A physically reasonable condition is to require the probability current to vanish at $x = 0$. If the Hamiltonian has the standard form, with a kinetic and a potential energy term, this condition has the general solution

$$\frac{\partial \psi}{\partial x}(x = 0) = \eta \psi(x = 0) \quad (9)$$

where η is a real parameter, independent of the center of mass coordinate and the function ψ . It can be interpreted as a statistics parameter, with $\eta = 0$ for bosons and $\eta = \pm\infty$ for fermions. Also in this case the effect of the statistics parameter can be transformed from a condition on the wave functions to a special type of interaction. If the wave functions are extended to symmetric functions on the full line, the effect of η can be expressed through a δ -function potential,

$$V_{\text{stat}} = 2\eta \frac{\hbar^2}{m} \delta(x), \quad (10)$$

where m is the mass of the particles. The effect of this interaction can be illustrated by the harmonic oscillator Hamiltonian,

$$H = \frac{\hbar^2}{m} \left(-\frac{\partial^2}{\partial x^2} + 2\eta \delta(x) \right) + \frac{1}{4} m \omega^2 x^2. \quad (11)$$

The energy spectrum is given implicitly by the equation

Fig. 5 The lowest energy eigenvalues in the two cases discussed in the text, with (A) as first case and (B) as the second case. In (A) the eigenvalues are functions of the statistics parameter η' and in (B) they are functions of α_0 . Bosons have $\eta' = 0$ and $\alpha_0 = 1/4$, fermions have $\eta' = \pm 1$ and $\alpha_0 = 3/4$. From Leinaas JM and Myrheim J (1992) Heisenberg quantization for systems of identical particles. *International Journal of Modern Physics* 8: 3649.

$$\frac{\Gamma\left(\frac{3}{4} - (E/2\hbar\omega)\right)}{\Gamma\left(\frac{1}{4} - (E/2\hbar\omega)\right)} = -\eta\sqrt{\frac{\hbar}{2m\omega}}. \quad (12)$$

Solutions to this equation are shown in Fig. 5A. The spectrum is a periodic function of η in the interval $[-\infty, +\infty]$, in the sense that it is the same at both endpoints of the interval. But the periodic behavior is nontrivial in the sense that all levels move upward by one unit, while a new state appears from the infinite bottom and moves upward to take the place of the ground state.

The one-dimensional δ -function interaction between otherwise free bosons is known as the Lieb–Liniger model, and it was solved exactly in the general case of N particles in 1963 (Lieb and Liniger, 1963; Lieb, 1963).

The definition of one-dimensional anyons sketched above is not the only definition which is possible. While the former is based on the use of the wave function, another approach is possible, which is based on the observables x and p . For a single spinless particle, all observables are functions of these two. However, for two identical particles the relative position x and momentum p cannot be regarded as observables, since, if that was the case, they could be used to distinguish the two particles. Instead, the quadratic variables x^2 , p^2 , and xp , which are symmetric under interchange, can be used as the fundamental set of observables. They define a closed algebra under commutation, and if the following linear combinations are used,

$$\begin{aligned} A &= (1/4\omega)(p^2 + \omega^2 x^2), \\ B &= (1/4\omega)(p^2 - \omega^2 x^2), \\ C &= (1/4)(xp + px), \end{aligned} \quad (13)$$

where ω is arbitrary, the corresponding commutators are (with $\hbar = 1$)

$$[A, B] = iC, \quad [B, C] = -iA, \quad [C, A] = iB. \quad (14)$$

See Leinaas and Myrheim (1992). This is the noncompact version of the standard $\mathfrak{su}(2)$ algebra.

Quantization of the system means defining an irreducible representation of the algebra. The operator A is then essentially the Hamiltonian of a harmonic oscillator, and $B_{\pm} = B \pm iC$ are raising and lowering operators in a ladder of eigenvalues of A . The commutator relations then imply for the eigenvectors of A ,

$$A|\alpha_n\rangle = \alpha_n|\alpha_n\rangle, \quad B_{\pm}|\alpha_n\rangle = \beta_{n\pm}|\alpha_n \pm 1\rangle, \quad (15)$$

and the eigenvalues of A are

$$\alpha_n = \alpha_0 + n \quad (16)$$

where α_0 is a positive number and n is a nonnegative integer. Comparing with the standard description we find that bosons correspond to $\alpha_0 = \frac{1}{4}$ and fermions to $\alpha_0 = \frac{3}{4}$, but there is no obvious reason to restrict α_0 to these two values. So α_0 defines a continuous statistics parameter in the one-dimensional case, but this parameter, which is dimensionless, is not related to the dimensional parameter η , introduced before, in any simple way. However, as Eq. (12) shows, the expression $\eta\sqrt{\hbar/2m\omega} \equiv \tilde{\eta}$ is dimensionless, and in Fig. 5A, $\eta' \equiv (2/\pi) \arctan \tilde{\eta}$ is used as the variable corresponding to α_0 in Fig. 5B.

Thus, there are two different approaches to the quantization of the one-dimensional system and two different statistics parameters η' and α_0 . To illustrate better the difference, we may consider the spectrum of the harmonic oscillator also in the

wave function approach. In this case the effect of the statistics parameter can also be represented as a statistics interaction, but it has the form $1/x^2$ rather than a δ -function potential. The Hamiltonian of the relative motion is then

$$H = \frac{\hbar^2}{m} \left(-\frac{d^2}{dx^2} + \frac{\lambda}{x^2} \right) + \frac{1}{4} m \omega^2 x^2 \quad (17)$$

with

$$\lambda = 4 \left(\alpha_0 - \frac{1}{4} \right) \left(\alpha_0 - \frac{3}{4} \right). \quad (18)$$

The spectrum is essentially the same as for the A operator,

$$E_n = 2\hbar\omega(\alpha_0 + n) \quad (19)$$

There is some resemblance with the spectrum depending on η' , but in the present case the spectrum is only quasi-periodic in α_0 since no state moves in to replace the lowest energy state which is lost when α_0 is increased by one unit. However, the spectrum is simpler than with the δ -function potential since there is a constant difference between the neighboring levels for all values of the statistics parameter.

The one-dimensional inverse square interaction is another model which is exactly solvable for N particles, it is known as the Calogero (or Calogero–Sutherland) model (Calogero, 1971).

Anyons and the fractional quantum Hall effect

In our three-dimensional world the elementary particles are restricted to be either fermions or bosons. However, in condensed matter physics, the creation of quasi two-dimensional systems is possible, and in such systems anyons may emerge. They are then excitations of the quantum system with sharply defined particle properties, generally known as quasiparticles. The presence of anyons in such systems is not only a theoretical possibility, as was realized after the discovery in 1982 by D.C. Tsui, H.L. Stormer, and A.C. Gossard, of the *fractional* quantum Hall effect (Tsui et al., 1982). This effect is caused by the formation of a two-dimensional, incompressible electron fluid in a strong magnetic field.

The integer quantum Hall effect, Fig. 6, can be understood without taking electron–electron interactions into account. However, such interactions are crucial for the existence of a mobility gap in the case of partially filled Landau levels. In his pioneering paper (Laughlin, 1983), R.B. Laughlin concentrated on the filling fractions $\nu_m = 1/m$, with m as an odd integer, and introduced the following wave function for the ground state

$$\Psi_m = \prod_{k < l}^N (z_k - z_l)^m e^{-\frac{1}{2} \sum_{i=1}^N |z_i|^2} \quad (20)$$

This function describes the expected properties of the ground state very well. The charge is distributed uniformly throughout the plane, with approximate radius $R = \sqrt{mN}$. Furthermore, as shown by Laughlin the state is incompressible and thereby gives the existence of the desired mobility gap.

Fig. 6 The integer quantum Hall effect. The longitudinal and Hall resistivities are shown as functions of the magnetic field. The plateaus appear where a number of Landau levels are filled. In the *fractional* quantum Hall effect, new plateaus appear between those of the filled Landau levels. From <https://www.nobelprize.org/prizes/physics/1998/press-release/>.

Fig. 7 The quasi-hole charge, in electron units, is measured within a variable radius R . The background system is composed of 100 electrons in the form of a circular droplet. For small R , there is a region where the charge builds up when R increases. In an intermediate region the charge seems to stabilize at a constant value, consistent with the expected value $-1/3$, and for larger R there is a region where the charge again decreases to zero. From Kj nsberg H and Leinaas JM (1999) Charge and statistics of quantum Hall quasi-particles-numerical study of mean values and fluctuations. Nuclear Physics B 559: 705.

Laughlin also proposed the following functions for the quasi-hole and quasi-electron states,

$$\begin{aligned}\Psi_m^{qh} &= e^{-\frac{1}{2}\sum_{i=1}^N |z_i|^2} \prod_{j=1}^N (z_j - z_0) \prod_{k<l}^N (z_k - z_l)^m \\ \Psi_m^{qe} &= e^{-\frac{1}{2}\sum_{i=1}^N |z_i|^2} \prod_{j=1}^N (\partial_{z_j} - z_0^*) \prod_{k<l}^N (z_k - z_l)^m\end{aligned}\quad (21)$$

Numerical studies of the Laughlin states have later been performed (Kj nsberg and Myrheim, 1999; Kj nsberg and Leinaas, 1999), and the results for the Laughlin quasi-hole states are in good agreement with what is expected (see Fig. 7). However, in the case of the Laughlin quasi-electron state, the results are not equally good. Other proposed functions for the quasi-electron states, introduced by Jain (1989, 2020), show in this case better numerical results.

Not long after the Laughlin states were introduced, the anyon character of the quasiparticles in this system was demonstrated quite convincingly in theoretical studies by Halperin (1984) and Arovas et al. (1984). These observations were the starting point for the still ongoing interest in the physics of anyons, and later for the possible use of anyons in technological applications.

Although the theoretical results have strongly supported the idea of the presence of anyons in the fractional quantum Hall effect, a direct experimental evidence for the existence of anyons has, until recently, been lacking. However, in 2020, two teams of scientists, in Paris (Bartolomei et al., 2020) and at Purdue (Nakamura et al., 2020), announced experimental evidence for the existence of anyons. In the Paris group, presence of fractional statistics at filling factor $\nu = 1/3$ was demonstrated by measuring current correlations in collisions between anyons at a beam splitter. The Purdue group, on the other hand, used an electronic Fabry-Perot interferometer to demonstrate the presence of anyonic statistics, also in this case with a $\nu = 1/3$ fractional quantum Hall state. Experimental attempts had been done before, such as in Camino et al. (2005), but in these cases, clear signatures of anyons were missing due to possible interference with other sources. In the new experiments these problems were eliminated.

The anyons discussed so far are often referred to as *abelian* anyons. This means that the statistics phase factors are abelian representations of the braid group. This is so, since the wave functions of the anyons in the *in* and *out* configurations are assumed to be identical up to a phase factor, as a consequence of the particles being identical. However, nonabelian representations of the braid group exist, and they can be viewed as describing a new type of anyons, named nonabelian anyons, or simply *nonabelions*.

The additional degrees of freedom in this case are not associated with each anyon separately, and therefore they do not change the criteria of indistinguishability. Instead it is associated with the field of electrons which form the background of the anyons, and the change in the background is obtained by braiding of the anyons. This gives an extension of the simple identical particle picture of anyons, since new degrees of freedom in a sense are shared by the participants of the braid. In the rich physics of the quantum Hall effects there are indications that such nonabelions may indeed exist (Wen, 1991; Moore and Read, 1991), and theoretical ideas of exploiting such objects in the form of topological quantum computation (Kitaev, 2003) have gained much interest.

Conclusion

We have presented very briefly the reasoning leading to theories of fractional statistics in one and two dimensions. The two-dimensional case is most familiar, since it finds application to the fractional quantum Hall effect. The one-dimensional case is different, in that the particle statistics is expressed as a boundary condition on the wave function. We do not know of physical applications of the one-dimensional theory.

Abstract

Quantum statistics refers to the properties of the wavefunction under the exchange of two particles. In three dimensions, there are two categories of particles depending on the value of the phase φ acquired by the wavefunction in the exchange process: bosons satisfy $\varphi = 0$ and fermions $\varphi = \pi$. In contrast, two-dimensional systems can host quasiparticles called anyons that obey intermediate, or fractional, statistics between fermions and bosons, with $0 \leq \varphi \leq \pi$. As a result, and contrary to fermions and bosons, anyons have non trivial braiding properties. It means that the phase factor $e^{2i\varphi}$ accumulated by the wavefunction when one anyon encircles another one is different from 1. The fractional quantum Hall effect, which occurs in high mobility two-dimensional electron gases placed in a strong perpendicular magnetic field, is one of the systems which hosts anyons. They carry a fractional charge and obey fractional statistics. The fractional charge of anyons was measured in the 1990s from the noise generated by partitioning an anyon beam at a beam splitter. We discuss here the recent demonstration of their fractional statistics in an anyon collider at the filling factor $\nu = 1/3$ of the fractional quantum Hall effect. In anyon collision experiments, two dilute beams of anyons generated randomly by two anyon sources collide on a beam splitter. For comparison with the anyon case, we present first bosonic and fermionic collisions. They are governed by boson bunching and fermion antibunching between two particles colliding simultaneously at the splitter. In the anyon case, specific mechanisms for charge transfer at the beam splitter occur, which are governed by the anyon braiding factor $e^{2i\varphi}$. In these mechanisms, a single anyon emitted at the splitter input may trigger the bunching of another anyon in the same output, leaving a hole in the other output. We discuss in this manuscript how these specific anyon transfer mechanisms, which lead to strong negative cross-correlations of the current fluctuations at the splitter output, are used to distinguish anyon collisions from the bosonic and fermionic cases. We also discuss how the dependence of the noise correlations in the anyon braiding phase is used to quantitatively investigate the fractional exchange phase φ of anyons in colliders.

Key points

- In three dimensions, particles are divided into two categories depending on the phase φ acquired by the wavefunction when two particles are exchanged. Bosons satisfy $\varphi = 0$ and tend to bunch together, fermions satisfy $\varphi = \pi$ and tend to exclude each other. The properties of particles with respect to particle exchange operations are called the quantum statistics
- In two dimensions, other particles with intermediate values of the exchange phase, $0 < \varphi < \pi$, may exist and are called anyons.
- In a braid operation one particle encircles another particle. In a braid operation, the many-body wavefunction acquires the phase 2φ . Bosons and fermions thus have trivial braid operations: $e^{i2\varphi} = 1$. Anyons have nontrivial braid operations: $e^{i2\varphi} \neq 1$.
- Colliders can characterize the quantum statistics of the colliding particles, bosons, fermions, and anyons. As no deterministic source of anyons is available at the moment, the direct comparison of bosonic, fermionic, and anyonic (also called fractional) statistics in collision experiments requires the use of random sources of particles.
- Boson collisions are characterized by boson bunching at the collider output, leading to negative cross-correlations of the current fluctuations. Fermion collisions are characterized by fermionic antibunching, resulting in the suppression of the current cross-correlations. In the two cases, boson bunching and fermion antibunching require one particle to be emitted at each input of the collider. As a consequence, the current cross-correlations show a characteristic dependence in the square of the probability to emit the particles.
- Specific charge transfers at the beam splitter need to be taken into account the anyon case. One specific mechanism is a backward tunneling process, where a single anyon emitted by the source drags with him another anyon in one output of the beam splitter, leaving a hole in the other output. This mechanism corresponds to the bunching of two anyons in a given output of the splitter and is thus associated with negative cross correlations of the current fluctuations, as in the bosonic

case. However, contrary to the bosonic case, the emission of a single anyon in one input of the splitter is enough to trigger this bunching mechanism. The current cross correlations are thus directly proportional to the probability to emit the particles (contrary to its square in the bosonic and fermionic cases).

- The specific charge transfers in an anyon collision are directly mediated by the nontrivial braiding factor of anyons $e^{2i\varphi} \neq 1$ (and thus do not exist in the boson and fermion cases). Anyon collisions can thus be used to quantitatively measure the fractional statistics of anyons and their exchange phase φ . In particular the fractional statistics of anyons at the filling factor $\nu = 1/3$ of the fractional quantum Hall effect, with $\varphi = \pi/3$ has been demonstrated by several experiments.
- Anyon collisions can be extended, in principle, to the characterization of non-abelian anyons.

Introduction

In three-dimensional systems, there are only two categories of elementary excitations depending on the phase φ accumulated by the many-body wavefunction while exchanging two particles. Bosons, with $\varphi = 0$, tend to bunch together, whereas fermions, with $\varphi = \pi$, antibunch and follow Pauli's exclusion principle. In contrast, two-dimensional systems can host quasiparticles with quantum statistics intermediate between fermions and bosons (Leinaas and Myrheim, 1977; Wilczek, 1982b). As their exchange phase φ can take any value between 0 and π , these quasiparticles have been named anyons (Wilczek, 1982a). The fractional value of φ/π has important consequences when one performs a braiding operation, which consists in moving one particle around another one, thereby accumulating the phase 2φ . In the case of fermions ($\varphi = \pi$) or bosons ($\varphi = 0$), the accumulated braiding phase is trivial, with $e^{i2\varphi} = 1$. By contrast, anyons keep a memory of braiding operations as $e^{i2\varphi} \neq 1$. The stability of the braiding phase with local deformations of the anyon trajectories is at the origin of topologically protected quantum computing using non-abelian anyons (Kitaev, 2003; Nayak et al., 2008).

The fractional quantum Hall effect (Tsui et al., 1982; Laughlin, 1983), obtained by applying a strong magnetic field perpendicular to a high mobility two-dimensional electron gas, is one of the physical systems predicted to host anyons. We focus in this article on the Laughlin series (Laughlin, 1983), of fractional quantum Hall states, where the filling ν of the first Landau level satisfies $\nu = 1/m$ where m is an odd integer. In this situation, anyons are predicted to carry a fractional charge $e^* = e/m$ (Laughlin, 1983) and to obey fractional statistics with a fractional value of the exchange phase $\varphi = \pi/m$ (Halperin, 1984; Arovas et al., 1984). For Laughlin states, a single topological number m thus describes the conductance quantization, the fractional charge, and the fractional statistics of anyons: $G/G_0 = e^*/e = \varphi/\pi = 1/m$, where $G_0 = e^2/h$ is the conductance quantum.

We discuss in this article charge transport experiments, where the properties of anyons are characterized from the fluctuations of the electrical currents flowing in a fractional quantum Hall sample. In the fractional quantum Hall effect, the bulk of the sample is insulating and charge transport occurs along gapless one-dimensional chiral channels located at the edge of the sample. For Laughlin states, the edge structure is simple with a single edge channel of conductance $G = G_0/m$ along which charge propagates ballistically on very long distances (larger than the characteristic size of samples). Backscattering between two counterpropagating edge channels can be induced by using a quantum point contact (QPC), see Fig. 1. It consists of two metallic split gates deposited on top of the electron gas and capacitively coupled to it. Applying a negative voltage to the split gates brings the two edge channels close to each other, allowing elementary excitations to tunnel from one edge channel to the other. In the integer quantum Hall effect, these elementary excitations are electrons. In contrast, when the backscattering probability T of the QPC is small ($T \ll 1$), anyons of fractional charge are randomly emitted by quantum point contacts in the fractional quantum Hall regime. The random generation of anyon currents by QPCs in the fractional quantum Hall effect was used to measure the anyon fractional charge e^* . The classical random partitioning of anyons leads to a current noise $S_p = 2e^* I_T$ (Kane and Fisher, 1994; Chamon et al., 1995). Measuring

Fig. 1 Sketch of noise experiments using quantum point contacts. The two metallic split gates are represented in *gold* and the ballistic chiral edge channels in *red*. The *gray squares* are the ohmic contacts used as sources and drains of electrical currents. A dc voltage bias V_1 is applied to contact 1 to generate a noiseless current I_1^0 towards the QPC. The random transfer of anyons from one edge to the other is represented by the tunneling current I_T . The backscattering transmission of the QPC is defined as $T = \partial \rho / I_T$. The fluctuations of the currents at the output of the QPC are given by the random partition noise proportional to the charge e^* : $S_p = 2e^* I_T$ where I_T is the average tunneling current (in this example, $I_4 = I_T$).

the slope of the current noise with the current tunneling through the QPC I_T (also called the backscattered current in these experiments) allowed for the measurement of the anyon fractional charge $e^* = e/3$ at filling factor $\nu = 1/3$ (de-Picciotto et al., 1997; Saminadayar et al., 1997).

These experiments can be seen as a demonstration of the existence of anyons, as the theory predicts consistently their fractional charge and their fractional statistics. However, it did not directly probe the fractional exchange phase $\varphi = \pi/m$ of anyons. Recent heat conduction measurements at the filling factor $\nu = 5/2$ showed evidence of a non-abelian state (Banerjee et al., 2018), though these results give only indirect evidences of the underlying quantum statistics. In 2020, two different experiments provided a direct probe of the fractional statistics of anyons at the filling factor $\nu = 1/3$. Nakamura et al. (2020) investigated manifestations of fractional statistics using single-particle Fabry–Perot interferometry (Chamon et al., 1997), whereas Bartolomei et al. (2020) investigated these manifestations using two-particle Hanbury Brown and Twiss interferometry (Safi et al., 2001; Vishveshwara, 2003; Kim et al., 2005; Vishveshwara and Cooper, 2010; Campagnano et al., 2012, 2013) in the geometry of the anyon collider (Rosenow et al., 2016). This article focuses on the description of anyon collision experiments. It starts with a review of fermion and boson collisions in order to highlight the differences with the anyonic case. It then turns to the anyon case, focusing on the Laughlin state $\nu = 1/3$ and discussing first elements of theory before presenting the experimental results.

Fermion and boson collisions

Two-particle interference experiments have been first introduced in the context of quantum optics by Hanbury Brown and Twiss (Hanbury Brown and Twiss, 1954, 1956). Contrary to single-particle interferometry where interferences are characterized by the measurement of the average current at the output of an interferometer, two-particle interferences are revealed by the measurement of current–current correlations at the output of a beam splitter. The geometry of a collision experiment is represented in Fig. 2A, where two sources are placed at the input of a beam splitter and one measures the cross-correlations of the current fluctuations at the splitter outputs S_{34} . In the context of optics, where such measurements have first been introduced, the correlations of the light intensity fluctuations are measured. In the context of quantum electronics, the electrical current plays the role of the light intensity in optics. Introducing $\delta I_3(t)$ and $\delta I_4(t)$ the electrical current fluctuations at time t in outputs 3 and 4, we discuss here the low-frequency correlations of the current fluctuations S_{34} defined by:

$$S_{34} = 2 \int d\tau \langle \delta I_3(t) \delta I_4(t + \tau) \rangle \quad (1)$$

Fig. 2 (A) Collision experiment with single boson (left) and fermion (right) sources. Source 1 and source 2, placed at input 1 and 2 of a beam splitter with transmission T , emit single particle wave packet of temporal extension τ_e . One measures the output current cross-correlations S_{34} as a function of the time delay τ between the arrivals of particles emitted by source 1 and source 2 at the beam splitter. Left: boson bunching. Two particles exit in the same output of the splitter (output 4), leading to an excess current in 4 together with a deficit of current in 3. The current cross-correlations S_{34} are negative. Right: fermion antibunching. Two particles exit in different outputs of the splitter, leading to a suppression of the current fluctuations. The current cross-correlations S_{34} vanish. (B) Current cross-correlations S_{34} as a function of the time delay τ . For $\tau \gg \tau_e$, the cross-correlations are given by the classical random partitioning of particles on the splitter: $P(\tau \gg \tau_e) = -1$. For $\tau \leq \tau_e$, two-particle interferences take place. In the bosonic case (left), boson bunching leads to a dip in the cross-correlations, $P(\tau = 0) = -2$. In the fermionic case (right), fermion antibunching leads to a peak of the cross-correlations, which are suppressed, $P(\tau = 0) = 0$.

In the boson and fermion cases, collision experiments have been implemented using triggered single-photon (in the bosonic case) or single-electron (in the fermionic case) sources that periodically emit a single particle with unit probability. Considering first the case where a single source is plugged at input 1 of the collider, the random partitioning of particles at the beam splitter results in fluctuations of the output currents that can be computed from a classical binomial partitioning process $S_{34} = -S_{rp}$, with $S_{rp} = 2qT(1 - T)I_1$, where I_1 is the current generated by source 1, q is the charge of the emitted particles, and T is the backscattering probability of the beam splitter. Using $I_T = TI_1$, S_{rp} can be rewritten as $S_{rp} = 2qI_T(1 - T)$, which is identical to the expression introduced in the previous section in the weak-backscattering limit $T \ll 1$. Note that this calculation is obviously specific to the case of charged particles, such as electrons. It needs to be adapted in the photon case, replacing the electrical current by the light intensity.

In the case where two sources are plugged at inputs 1 and 2, one measures the output cross-correlations as a function of the time delay τ between the arrival time of both particles at the beam splitter. For long time delay τ , larger than the temporal width τ_e of the emitted wave packets, there is no overlap between particles emitted by source 1 and source 2 at the beam-splitter and two-particles interferences are suppressed. One then recovers the classical result, $S_{34} = -S_{rp}$ with $S_{rp} = 2qT(1 - T)I_+$, where I_+ is the sum of the currents generated by the two sources, $I_+ = I_1 + I_2$. Introducing the Fano factor $P(\tau)$ defined as the current cross-correlations normalized by the classical random partition noise, $P(\tau) = S_{34}(\tau)/S_{rp}$, one has $P(\tau \gg \tau_e) = -1$ independently of the bosonic or fermionic nature of the colliding particles. For short time delays, $\tau \leq \tau_e$, two-particle interferences occur leading to different results for bosons and fermions due to their different statistics. In the bosonic case (left panel of Fig. 2) the probability to have two bosons bunching together in the same output of the beam splitter is doubled compared to the classical case (where effects of quantum statistics would be absent). The formation of packets of two bosons in the same output leads to more negative cross-correlations with $P(\tau = 0) = -2$ (see left panel of Fig. 2B). This dip in the cross-correlations in the bosonic case for short time delays is called the Hong-Ou-Mandel (HOM) dip in reference to the seminal photon collision experiments (Hong et al., 1987). On the contrary for fermions (see right panel of Fig. 2), antibunching results in a suppression of the cross-correlations of the current fluctuations $P(\tau = 0) = 0$ (see right panel of Fig. 2B). As two electrons always exit in different outputs, the random fluctuations of the current are suppressed, resulting in a Pauli peak of the cross-correlations at short time delays. The suppression of the noise in electron collisions due to fermionic antibunching has first been observed using continuous stationary electron sources (Liu et al., 1998) and more recently using triggered single electron sources (Ol'Khovskaya et al., 2008; Bocquillon et al., 2013; Dubois et al., 2013) implementing the electronic analogue of the HOM experiment.

The collider with random sources

Contrary to the fermionic and bosonic cases, deterministic single anyon sources have not been developed at the present time. However, as used for the measurement of the fractional charge of anyons, QPCs tuned in the weak backscattering regime (regime where the backscattering probability T is much smaller than one) in the fractional quantum Hall effect can be used as random Poissonian emitters of anyons (Martin, 2005). In particular, at the filling factor $\nu = 1/3$, the backscattering of a stationary current I_0 by a QPC leads to the random emission of anyons with a fractional charge $e^* = e/3$ and a fractional exchange phase $\varphi = \pi/3$. By tuning the magnetic field to the regime of the integer quantum Hall effect, the same quantum point contact biased by a stationary current acts as a random source of electrons, which are the elementary excitations in the integer case. Comparing electrons and anyons in collisions thus requires to replace the deterministic sources of particles by random ones. This means that anyon collisions require the use of three QPCs, two QPCs being used as sources for anyon emission and another one as the beam splitter where particles collide.

The anyon collider has been introduced by Rosenow et al. (2016). It mimics the geometry of the electronic HOM experiments presented in the previous section, replacing the single electron emitters by QPCs used as random emitters of anyons. The sketch of the collider and the SEM picture of the device studied in Bartolomei et al. (2020) are represented on Fig. 3. Two noiseless currents I_1^0 and I_2^0 impinging on QPC1 and QPC2, tuned in the weak backscattering regime with emission probabilities T_1 and T_2 , lead to the random generation of particles. The emitted particles then propagate toward a third QPC, cQPC, used as the beam splitter in the collision process. One measures the cross-correlations between the output currents, S_{34} , as a function of the experimental parameters: the input currents I_1 and I_2 and the backscattering probability T of cQPC. By changing the value of the magnetic field, two different types of collisions can be implemented. In the integer quantum Hall regime, the particles tunneling at QPC1 and QPC2 are electrons with fermionic statistics. In contrast, in the fractional quantum regime, the colliding particles are anyons with fractional statistics, offering the possibility to compare in the same setup the anyonic situation with the fermionic one. Two different configurations of the collider will be studied, differing by the imbalance between the currents I_1 and I_2 at the collider inputs. The balanced collider corresponds to symmetric bias of the collider inputs: $I_1^0 = I_2^0$ and $T_1 = T_2$. As both sources have the same emission probability in this case, we introduce the notation $T_S = T_1 = T_2$. The balanced configuration is thus characterized by a vanishing current difference between the inputs, $I_- = I_1 - I_2 = 0$, such that the current cross-correlations only depend on the total incoming current, $I_+ = I_1 + I_2$. The unbalanced case is obtained by increasing the imbalance ratio I_-/I_+ . In particular, the fully unbalanced case corresponds to $I_- = I_+$, where one source (e.g., source 2) has been switched off ($I_2 = 0$).

Random collisions of electrons

For comparison with the anyonic case, it is useful to discuss first the results of boson and fermion collisions described in Section "Fermion and boson collisions" in the case where random sources of particles replace the deterministic ones. The bosonic

Fig. 3 (A) Sketch of the collider. Charge transport occurs along the ballistic and chiral edge channels represented in *red*. The voltage sources V_1 and V_2 generated the noiseless stationary currents I_1^0 and I_2^0 . The partitioning of these currents by QPC1 and QPC2 leads to the random emission of particles (electrons for integer filling factor, anyons in the fractional case) with probabilities T_1 and T_2 . The emitted particles propagate toward a third quantum point contact, cQPC, of backscattering transmission T , and which plays the role of the beam splitter in the collision. (B) Colored scanning electron microscope picture of the collider sample. The two-dimensional electron gas is represented in blue and edge channels in *red*. The metallic gates (QPC1, QPC2, and cQPC) are presented in *gold color*.

and fermionic situations can be described by a simple classical model (Rosenow et al., 2016), where source 1 (respectively source 2) emits one particle with probability T_1 (respectively T_2) at input 1 (respectively 2) of the collider. The probability that a source does not emit a particle is $1 - T_i$ ($i = 1, 2$) meaning that the probability that one source emits two particles is neglected (it is forbidden in the fermion case by the Pauli exclusion principle). In relation with the experiment, T_1 and T_2 are the backscattering probabilities of QPC1 and QPC2. In order to take into account the bosonic and fermionic statistics of particles, one can weigh the classical probability to have two particles in a given output (e.g. output 1), $P(2, 0) = T(1 - T)T_1T_2$, by a factor $1 - p$, where p encodes the effect of fermionic and bosonic statistics. $p = +1$ for fermions: due to Pauli exclusion principle, electrons are forbidden to exit in the same output and $P(2, 0) = 0$. $p = -1$ for bosons: bosons tend to bunch together such that the probability to have two particles in the same output is doubled compared to the classical case, $P(2, 0) = 2T(1 - T)T_1T_2$. Within this simple classical model, one can easily compute the current cross-correlations as a function of the incoming currents I_1 and I_2 .

We focus first on the case of the balanced collider, $I_- = I_1 - I_2 = 0$. In this case, the current cross-correlations increase linearly with the total current $I_+ = I_1 + I_2$:

$$S_{34} = -2qT(1 - T)I_+(1 - p)Ts \quad (2)$$

$$P_{cl}(I_- = 0) = S_{34}/S_{rp} = -(1 - p)Ts, \quad (3)$$

where, as in Section “Fermion and boson collisions,” the Fano factor P_{cl} is defined by normalizing the cross-correlations by the classical random partition noise $S_{rp} = 2qT(1 - T)I_+$. As can be seen in Eq. (3), this classical model, which correctly describes the bosonic and fermionic cases, predicts a Fano factor that varies linearly with the emission probability T_S . In particular, it vanishes in the Poissonian limit of particle emission, $T_S \ll 1$, both in the fermionic and bosonic cases. This can be understood by the suppression of two-particle interferences related to the statistics of particles when the probability to have one particle in each collider input becomes vanishingly small. The results of Eq. (3) also extend the results discussed in the deterministic case ($T_S = 1$) in Section “Fermion and boson collisions” to the case of arbitrary emission probability T_S . The balanced regime of the random collider, $I_- = 0$ corresponds to the regime $\tau \ll \tau_e$ in the case of deterministic particle emission. In particular, in the fermionic case ($p = 1$), one recovers the suppression of the cross-correlations, $P_{cl,f}(I_- = 0) = 0$ due to fermionic antibunching. In the bosonic case ($p = -1$), negative cross-correlations are enhanced by bosonic bunching, $P_{cl,b}(I_- = 0) = -2T_S$, which correspond to a factor 2 enhancement compared to the case of distinguishable particles ($p = 0$ and $P_{cl,d} = -T_S$). In the case of emission with unit probability, $T_S = 1$, one recovers $P_{cl,b}(I_- = 0) = P(\tau = 0) = -2$.

In the opposite limit of the completely unbalanced collider, $I_- = I_+$, the classical model predicts $P_{cl}(I_- = I_+) = -T_1$. This single source regime is the counterpart, for random sources, of the regime $\tau \gg \tau_e$ in the case of deterministic sources. Two-particle interferences are suppressed and the result does not depend on the fermionic or bosonic nature of particles. In particular, one recovers $P_{cl}(I_- = I_+) = -1$ in the regime of emission with unit probability, $T_1 = 1$. That means that negative cross-correlations are restored in the fermionic case when one increases the imbalance ratio I_-/I_+ . Note that $P_{cl}(I_- = I_+) = -T_1$ can also be seen as a signature of a random Poissonian transfer of particles through cQPC in the limit $T \ll 1$. Introducing $S_{I_T I_T}$ the fluctuations of the tunneling current I_T at cQPC, S_{34} is related to $S_{I_T I_T}$ in the completely unbalanced regime by the relation $S_{34} = -S_{I_T I_T} + TS_{I_1 I_1}$, where $S_{I_1 I_1} = 2q(1 - T_1)I_1$ is the random partition noise resulting from the random particle emission at input 1 of cQPC. The first term in

the expression of S_{34} results from the random partitioning of particles at cQPC. The second term represents the current fluctuations at input 1 of cQPC that are transmitted toward the outputs 3 and 4. One then immediately obtains, when $T \ll 1$:

$$S_{I_1 I_T}(I_- = I_+) = 2qTT_1 I_1 + 2qT(1 - T_1)I_1 = 2qI_T \quad (4)$$

$$F_{cl}(I_- = I_+) = \frac{S_{I_1 I_T}}{2qI_T} = 1, \quad (5)$$

where one has introduced another Fano factor F_{cl} defined as the fluctuations of the tunneling current normalized by the Poissonian limit $2qI_T$ (Lee et al., 2022). Eq. (5) shows that, in the classical model and in the completely unbalanced case, where two-particle interferences are suppressed, the tunneling events at cQPC are completely uncorrelated. The regime of nonunit emission probability, $T_S \neq 1$, leads to an important hallmark of bosonic and fermionic collisions: $P_{cl}(I_-/I_+)$ is always proportional to the probability to emit particles. It means that $|P_{cl}(I_-/I_+)|$ decreases when T_S decreases. In particular, one has $P_{cl} \approx 0$ in the Poissonian limit for particle emission by sources 1 and 2: $T_1, T_2 \ll 1$. As shown by Eq. (3), P_{cl} is also proportional to T_S in the balanced case. It means that $P_{cl} \ll 1$ independently of the imbalance ratio I_-/I_+ in the regime $T_1, T_2 \ll 1$. As will be seen in Sections “The anyon collider: Elements of theory” and “The anyon collider: Experimental results,” the results are completely different in the anyon case.

The predictions of the classical model in the fermionic case can be directly compared with experiments by setting the magnetic field at an integer filling factor. We plot on Fig. 4A the results for electron collisions in the balanced configuration at the integer filling factor $\nu = 3$ (similar results are obtained for $\nu = 2$). The observed results are in very good agreement with the predictions in the fermionic case. For all the emission probabilities T_S , one observes $S_{34} \approx 0$. For small values of T_S , one even observes slightly positive cross-correlations, with an increase of S_{34} at low current I_+ followed by a plateau of zero slope, $P \approx 0$. These residual positive cross-correlations might be related to residual effects of Coulomb interactions between electrons (Idrisov et al., 2022) which are not taken into account in this simple model. As discussed in the previous sections, this suppression of the cross-correlations in the fermion case is the signature of fermionic antibunching due to the Pauli exclusion principle. It is striking to compare the cross-correlations plotted on Fig. 4A with the auto-correlations of the current fluctuations $(S_{33} + S_{44})/2$, plotted on Fig. 4B. For $T_S = 1$ (red empty circles), the input currents I_1 and I_2 are noiseless and both the auto- and cross-correlations vanish. When decreasing the emission probability T_S , the noise of the currents I_1 and I_2 increases, as can be seen by the increase of the current auto-correlations. The observed increase of the auto-correlations when decreasing T_S is perfectly captured by the classical model which predicts $P_{cl,auto} = (S_{33} + S_{44})/(2S_{pp}) = (1 - T_S)/(2T(1 - T))$ (red dashed line for $T_S = 0.7$ and orange dashed line for $T_S = 0.2$ on Fig. 4B). For the lowest value of $T_S = 0.2$, the auto-correlations reach values more than ten times larger than the cross-correlations, reflecting the role of fermionic antibunching in the suppression of the cross-correlations.

The variation of $P(I_-/I_+)$ with the imbalance ratio I_-/I_+ at filling factor $\nu = 3$ is plotted in Fig. 5A. As expected in the electron case, increasing the imbalance between the collider inputs restores negative cross-correlations. In addition, $|P(I_- = I_+)|$ decreases when one decreases the emission probability T_S . For $T_S = 1$, the input QPCs play no role (as they transmit electrons with unit probability) and one effectively implements a single QPC experiment. In this case, the noise equals the random partition noise generated by the voltage difference $V_1 - V_2$ (or the current difference I_-) applied between the inputs of cQPC: $S_{34} = -S_{pp} = -2eT(1 - T)I_-$. Due to the definition of P , where S_{34} is normalized by the factor $2eT(1 - T)I_+$, the value $P_{cl}(I_-/I_+)$ in the single QPC regime ($T_S = 1$) is thus given by $P_{1QPC}(I_-/I_+) = -I_-/I_+$ (black dashed line in Fig. 5A), independently of the statistics of the particles. For $T_S < 1$, $|P(I_- = I_+)|$

Fig. 4 Electron collisions, $\nu = 3$ and balanced configuration, $L = 0$. (A) Normalized cross-correlations, $S_{34}/(2eT(1 - T))$, as a function of the total emitted electron current I_+ . Four different values of the electron emission probability are plotted: $T_S = 1$, $T_S = 0.7$, $T_S = 0.35$ and $T_S = 0.2$. (B) Normalized current auto-correlations, $(S_{33} + S_{44})/(4eT(1 - T))$, as a function of the total emitted electron current I_+ for the same values of T_S plotted in panel (A). The auto-correlations are suppressed for $T_S = 1$ (as the emitted current is noiseless) and increase when T_S decreases. The predictions from the classical model are represented in red (for $T_S = 0.7$) and orange (for $T_S = 0.2$) dashed lines.

Fig. 5 Electron collisions, $\nu = 3$ as a function of the imbalance ratio L/L_+ . (A) Measurement of $P(L/L_+)$. At $L/L_+ = 0$, $P \approx 0$ as a result of fermionic antibunching. For $L/L_+ = 1$, negative cross-correlations are restored and $|P(L/L_+)|$ decreases when one decreases the emission probability T_S . The black dashed line corresponds to $P_{QPC}(L/L_+) = -L/L_+$, which is the expectation in a single QPC experiment (which is the limit obtained when $T_S = 1$). (B) $P(L = L_+)$ as a function of the source emission probability T_S . Data points follow the predictions from the classical model $P_{cl}(L = L_+) = -T_S$ (black dashed line), with $P(L = L_+ = 1)$ eventually going to zero for $T_S \ll 1$.

decreases, with vanishing values ($|P(L = L_+)| \ll 1$) in the Poissonian limit $T_S \ll 1$. Fig. 5B represents the evolution of $P(L = L_+)$ with T_S . The results agree very nicely with the prediction $P_{cl}(L = L_+) = -T_S$ from the classical model (black dashed line on Fig. 5B).

The anyon collider: Elements of theory

The case of anyon collisions cannot be described by the classical model presented in Section “The collider with random sources,” as specific mechanisms occur for particles with nontrivial braiding properties: $e^{i2\varphi} \neq 1$. A full quantum model of anyon collisions was first developed in Rosenow et al. (2016), using nonequilibrium bosonization techniques (Levkivskiy and Sukhorukov, 2009; Gutman et al., 2010), for the calculation of the tunneling current I_T at cQPC and of its fluctuations $S_{I_T I_T}$. Identical results for I_T and $S_{I_T I_T}$ were obtained recently using nonequilibrium Keldysh theory (Morel et al., 2022; Lee and Sim, 2022; Mora, 2022). These works also pointed the specific role of nontrivial anyon braiding in the computation of the tunneling current and of its fluctuations. We present and discuss here the results obtained in these various publications.

We first introduce the operators $\Psi_i^\dagger(x)$, which create an anyon at position x of the chiral edge channels $i = 1$ or $i = 2$. At equilibrium ($V_1 = V_2 = 0$) and at zero temperature, the edge channels 1 and 2 are characterized by the temporal correlator $\langle \Psi_i^\dagger(x, t) \Psi_i(x, 0) \rangle_{eq} = \frac{1}{(0^+ + it)^\delta}$, where $\delta/2$ is called the scaling dimension of the anyon creation operator $\Psi_i^\dagger$ and governs the power law of the temporal decay of the equilibrium correlation function. For a Laughlin state $\nu = 1/m$ with a simple edge structure, $\delta = 1/m$ is directly related to the topological order in the bulk. However, it may deviate from $1/m$ when edge reconstruction mechanisms leading to counterpropagating modes are present (Rosenow and Halperin, 2002).

In order to describe anyon transfers between edge channels 1 and 2 at cQPC, one introduces the anyon tunneling operator, H_T , at the location of cQPC assumed to be $x = 0$:

$$H_T = T + T^\dagger = \xi \Psi_2^\dagger(x=0) \Psi_1(x=0) + \xi^* \Psi_1^\dagger(x=0) \Psi_2(x=0), \quad (6)$$

where ξ is the tunneling amplitude. The calculation of the current cross-correlations at the output of the collider in the weak-backscattering limit for anyon tunneling at cQPC is then based on a perturbative calculation of the tunneling current and of its fluctuations at first order in the tunneling coupling $|\xi|^2$, when the conductor is driven out of equilibrium by the random Poissonian emission of anyons at inputs 1 and 2 of cQPC. As a result, the dominant contribution to the nonequilibrium correlations of the tunneling Hamiltonian, as well as the tunneling rates $W_{1 \rightarrow 2}$ and $W_{2 \rightarrow 1}$ describing anyon transfers between edge channel 1 and 2 are given by (Rosenow et al., 2016; Morel et al., 2022; Lee and Sim, 2022):

$$\langle T^\dagger(0) T(t) \rangle_{neq} = e^{-(1-e^{-2i\varphi})\frac{1}{4}t} e^{-(1-e^{2i\varphi})\frac{1}{4}t} \langle T^\dagger(0) T(t) \rangle_{eq} + \text{subleading terms}, \quad (7)$$

$$W_{1 \rightarrow 2} = \int_{-\infty}^{+\infty} dt \langle T^\dagger(0) T(t) \rangle_{neq} = \alpha \Re \left[e^{i\pi\delta} (I_1(1 - e^{-2i\varphi}) + I_2(1 - e^{2i\varphi}))^{2\delta-1} \right] \quad (8)$$

$$W_{2 \rightarrow 1} = \int_{-\infty}^{+\infty} dt \langle T(t) T^\dagger(0) \rangle_{neq} = \alpha \Re \left[e^{i\pi\delta} (I_1(1 - e^{2i\varphi}) + I_2(1 - e^{-2i\varphi}))^{2\delta-1} \right], \quad (9)$$

where α is a constant that will not play a role in the following. I_T and $S_{I_T I_T}$ can then be readily expressed as a function of the tunneling rates (Lee et al., 2022):

$$I_T = e^*(W_{1 \rightarrow 2} - W_{2 \rightarrow 1}) = -e^* \alpha \sin(\pi\delta) \Im [I_1(1 - e^{-2i\varphi}) + I_2(1 - e^{2i\varphi})]^{2\delta-1} \quad (10)$$

$$S_{I_T I_T} = 2e^{*2} (W_{1 \rightarrow 2} + W_{2 \rightarrow 1}) = 2e^{*2} \alpha \cos(\pi\delta) \Re [I_1(1 - e^{-2i\varphi}) + I_2(1 - e^{2i\varphi})]^{2\delta-1} \quad (11)$$

Eqs. (7), (8), and (9) show that, in the anyon case, the tunnel processes at cQPC explicitly depend on the braiding phase 2φ . Note that, although the phase 2φ is related to the braiding phase of bulk anyons by the bulk-edge correspondence, anyons at the edge are not protected by the gap that exists in the bulk. It means that 2φ may differ from the braiding phase of anyons in the bulk if, for example, the Coulomb interaction between several edge channels leads to charge fractionalization mechanisms (Safi and Schulz, 1995; Berg et al., 2009; Kamata et al., 2014; Inoue et al., 2014; Freulon et al., 2015). The resulting fractionalized charges may have different mutual fractional statistics (Lee et al., 2020), resulting in a modified value of the exchange phase φ at the output of the interedge interaction region (Levkivskiy, 2016; Idrisov et al., 2022). Note also that, in the case of bosonic or fermionic statistics discussed in the previous sections, the braiding phase is trivial, $2\varphi = 2n\pi$, such that $\langle T^\dagger(0)T(t) \rangle_{\text{neq}} = \langle T^\dagger(0)T(t) \rangle_{\text{eq}}$. One thus needs to compute the correlations of the tunneling Hamiltonian at the next leading order to capture its out of equilibrium contribution. It corresponds precisely to the classical model presented in Section “The collider with random sources,” showing that the mechanisms involved in anyon collisions are fundamentally different from the ones involved in the bosonic and fermionic cases.

Let us discuss first these mechanisms in the completely unbalanced configuration, $I_- = I_+$, where source 2 has been switched off ($I_2 = 0$). In this case the natural forward tunneling process is $W_{1 \rightarrow 2}$. It is represented in Fig. 6B: the random emission of anyons at input 1 of cQPC leads to the transmission of anyons from input 1 to input 2 at cQPC. However, in the anyon case, there is also a contribution of the reverse tunneling process, $W_{2 \rightarrow 1}$, represented on Fig. 6A, where the random emission of anyons at input 1 of cQPC triggers the tunneling of another anyon from edge channel 2 to edge channel 1. $W_{2 \rightarrow 1}$ is a bunching process which is specific to anyons, where two anyons bunch together in output 3 leaving an anti-anyon (or a hole) in output 4. $W_{2 \rightarrow 1}$ involves the interferences between processes where the anyons emitted by source 1 are transmitted toward output 3 before the emission of the anyon/anti-anyon pair at cQPC (see Fig. 6A), and processes where anyons emitted by source 1 are transmitted toward output 3 after the creation of the anyon/anti-anyon pair (see Fig. 6C). As discussed in Morel et al. (2022) and Lee and Sim (2022), this interference term can be viewed, see Fig. 6D, as time-domain interferences involving the braiding of anyons emitted by source 1 by anyons tunneling at cQPC. This explains why $W_{2 \rightarrow 1}$ and $W_{1 \rightarrow 2}$ explicitly depend on the braiding phase 2φ and why the reverse process $W_{2 \rightarrow 1}$ vanishes in the bosonic and fermionic cases.

In the balanced configuration $I_- = 0$, interference processes involving anyons emitted both by QPC1 and QPC2 need to be taken into account. Fig. 7A represents the interference term contributing to the tunneling rate $W_{2 \rightarrow 1}$ when both sources are switched on: the braiding processes occur in opposite directions for the two sources. This explains why the braiding phases 2φ are weighted by different signs in Eqs. (7), (8), and (9). It means that the contribution of the two sources do not add up and that there is an interference contribution which directly depends on the imbalance ratio I_-/I_+ .

Fig. 6 (A) Reverse tunneling process $W_{2 \rightarrow 1}$ at cQPC triggered by the emission of an anyon (represented in red) by source 1. In the reverse tunneling process, an anyon is created in edge channel 3 (represented in blue), leaving an anti-anyon (represented in white) in edge channel 4. In this process occurring with amplitude a_1 , the anyon emitted by source 1 is transmitted in 3 before the creation of the anyon/anti-anyon pair. (B) Forward tunneling process $W_{1 \rightarrow 2}$ at cQPC triggered by the emission of an anyon by source 1. In the forward tunneling process, an anyon is created in edge channel 4 (represented in blue), leaving an anti-anyon (represented in white) in edge channel 3. (C) Sketch of the reverse tunneling process occurring with amplitude a_2 where the transmission of the anyon emitted by source 1 toward output 3 and the creation of the anyon/anti-anyon pair are temporally exchanged compared to process a_1 (the red anyon is transmitted in 3 after the creation of the anyon/anti-anyon pair). (D) sketch of the interference term $a_1 a_2^*$ between process a_1 and process a_2 . The process can be seen as a braiding in time-domain of the anyon emitted by source 1 by the anyon generated at cQPC.

Fig. 7 (A) Sketch of the interference term $a_1 a_2^*$ contributing to the reverse tunneling $W_{2 \rightarrow 1}$ in the case where both source 1 and source 2 emit anyons toward cQPC (balanced collider case, $L = 0$). As represented on the sketch the braiding of anyons emitted by source 1 and source 2 occurs in opposite directions. (B) Predictions from Rosenow et al. (2016) for $P(L/I_+)$ in the case $\varphi/\pi = \delta = 1/3$. As illustrated by the sketch of panel (A), as braiding for source 1 and source 2 anyons occurs in opposite directions, braiding effects are less important in the balanced case $L = 0$ compared to the unbalanced case $L = I_+$ and $|P(L/I_+)|$ decreases when L/I_+ increases. The inset shows the dependence of $P(L = 0)$ when varying δ , keeping $\varphi/\pi = 1/3$ constant. The variations of P are small (less than 10%) in the range $1/3 \leq \delta \leq 2/3$ showing that P is rather insensitive to the value of δ in a wide range.

The current correlations at the output of the collider S_{34} can then be expressed as a function of the fluctuations of the tunneling current: $S_{34} = -S_{I_T I_T} + 2e^*(I_+ \partial_{I_-} + I_- \partial_{I_+}) I_T$. As already discussed in Section “Random collisions of electrons,” the second term entering the expression of S_{34} represents the transmission of the Poissonian noise generated by sources 1 and 2 from the inputs of cQPC toward outputs 3 and 4. In the balanced configuration, $L_- = 0$, it equals the classical random partition noise $2e^* T I_+$, where T is defined as $\partial_{I_-} I_T|_{I_-=0}$. The Fano factor P is then defined by the usual ratio: $P(I_-/I_+) = \frac{S_{34}}{2e^* T I_+}$. In the balanced configuration, a simple analytical expression for $P(I_- = 0)$ can be obtained (Rosenow et al., 2016):

$$P(I_- = 0) = 1 - \frac{\tan \varphi}{\tan \pi \delta} \frac{1}{1 - 2\delta} \quad (12)$$

Eq. (12) has two major differences with Eq. (3) in the classical case. First, it explicitly depends on the braiding phase φ of anyons. This stems from the role of time-domain interferences involving anyon braiding in the expression of the anyon tunneling rates. In particular, for a Laughlin state with $\varphi/\pi = \delta = 1/3$, one has $P(I_- = 0) = -2$, as experimentally observed in Bartolomei et al. (2020), see Section “The anyon collider: Experimental results.” The cross-correlations are strongly negative, showing that anyons tend to form larger packets of charges at the outputs of the beam splitter, as described by the tunneling processes $W_{1 \rightarrow 2}$ and $W_{2 \rightarrow 1}$. As discussed above, braiding effects occur in opposite direction and compensate each other when two sources are switched on (balanced case). One thus expects $P(I_-/I_+)$ to be even more negative when increasing the imbalance ratio L_-/I_+ . Fig. 7B shows the predictions for $P(L_-/I_+)$ as a function of L_-/I_+ in the Laughlin case $\varphi/\pi = \delta = 1/3$. Indeed $P(L_-/I_+)$ decreases when increasing L_-/I_+ , reaching $P(I_- = I_+) \approx -3.1$ in the completely unbalanced case. One might also wonder how $P(I_-/I_+)$ is predicted to vary when one changes the value of δ . This is particularly relevant as nonlinear $I - V$ characteristics in quantum point contacts fail to reproduce the expected power laws, which exponent is related to δ (Wen, 1991; Fendley et al., 1995). As plotted on the inset of Fig. 7B, P is predicted to have a very weak dependence on δ in a rather broad range of values, with less than $\pm 10\%$ variations in the range $0.3 \leq \delta \leq 0.7$. This shows that predictions for P are rather robust to the specific value of δ , which may deviate from $\delta = 1/3$ due to nonuniversal mechanisms.

There is a second important difference of Eq. (12) with the classical case. In the anyon case, $P(I_-/I_+)$ does not depend on the emission probabilities of source 1 and source 2. Indeed, in the classical case, boson bunching or fermion antibunching can only be present if both source 1 and source 2 emit particles, leading to a proportionality of the current cross-correlation to the product T_S^2 , such that P_{cl} is proportional to T_S (as one factor T_S is absorbed by the normalization by the total input current I_+). In the anyon case, the mechanism governing anyon bunching is completely different. The emission of an anyon by source 1 may trigger the transfer of another anyon from channel 2 (leaving a hole behind) to channel 1, leading to the bunching of two anyons in the same output. This process is present even when a single anyon source is switched on, leading to cross-correlations S_{34} proportional to T_S and a Fano factor independent of T_S . This provides a way to clearly identify anyon collisions and distinguish them from the classical bosonic and fermionic cases.

Before turning to the presentation of the experimental results, it is worth discussing another possible definition of a Fano factor that was introduced in Lee et al. (2022) and already discussed in the electron case in Section “Random collisions of electrons.” It is defined from the ratio of the fluctuations of the tunneling current $S_{I_T I_T}$ to the Poissonian limit for the noise:

$$F = \frac{S_{I_T I_T}}{2e^* I_T} = \frac{W_{1 \rightarrow 2} + W_{2 \rightarrow 1}}{W_{1 \rightarrow 2} - W_{2 \rightarrow 1}} \quad (13)$$

This second definition is more adapted to the study of the completely unbalanced case, $I_- = I_+$. In particular, it cannot be used in the balanced configuration as the tunneling current vanishes in this case, leading to diverging values of $F(I_- = 0)$. In the unbalanced case ($I_- = 0$), it illustrates the specific role of the bunching mechanisms, $W_{2 \rightarrow 1}$. When these bunching mechanisms are absent, $W_{2 \rightarrow 1} = 0$, one has immediately $F = 1$ which corresponds to classical Poissonian fluctuations of the tunneling current that are predicted by the classical model of collisions in the unbalanced configuration, see Eq. (5). In the case where the bunching mechanisms are present, $W_{2 \rightarrow 1} \neq 0$, one has immediately $F > 1$, showing super-Poissonian fluctuations of the tunneling current that are the counterpart of the strong negative values of $P(I_- = I_+)$. Similarly to $P(I_- = 0)$, a simple analytical expression for $F(I_- = I_+)$ can be obtained as a function of φ and δ : $F(I_- = I_+) = \cot(\pi\delta) \cot[(\pi - 2\varphi)(1/2 - \delta)]$. In particular, in the case of the Laughlin state $\varphi/\pi = \delta = 1/3$, one has $F(I_- = I_+) = 3.274$, as experimentally verified in Lee et al. (2022).

The anyon collider: Experimental results

We now discuss experimental results of Bartolomei et al. (2020) and Ruelle et al. (2022) for anyon collisions at the filling factor $\nu = 1/3$. We first present the results obtained in the balanced configuration ($I_- = 0$). QPC1 and QPC2 are tuned at equal transmissions T_S in the weak backscattering limit, $T_S \ll 1$, which is the regime for anyon emission. Fig. 8A represents the evolution of the normalized current cross-correlations $S_{34}/(2e^*T(1-T))$ (with $e^* = e/3$) as a function of the total input anyon current I_+ , for different values of the emission probability $T_S = 0.05$, $T_S = 0.15$ and $T_S = 0.25$. As can be seen on the figure, the normalized cross-correlations are strongly negative, and have a linear evolution with I_+ .

Fig. 8 Anyon collisions $\nu = 1/3$ and balanced configuration. (A) Normalized cross-correlations, $S_{34}/(2e^*T(1-T))$, as a function of the total emitted anyon current I_+ . Four different values of the emission probability are plotted: $T_S = 1$, $T_S = 0.25$, $T_S = 0.15$, and $T_S = 0.05$. The normalized cross-correlations are suppressed for $T_S = 1$ but strongly negative in the three other cases, with a slope close to $P = -2$ (blue dashed line). (B) Normalized current auto-correlations, $(S_{33} + S_{44})/(4e^*T(1-T))$, as a function of the total emitted anyon current I_+ for the same values of T_S plotted in panel (A). The blue and cyan dashed lines represent the predictions of the classical model for $T_S = 0.25$ and $T_S = 0.05$. (C) Measurements of the slope P for $T_S = 0.05$ as a function of cQPC's backscattering probability T . All the measured values are close to the prediction $P = -2$. (D) Measurements of $T = \partial I_- / \partial I_+|_{I_- = 0}$ as a function of the total input current I_+ . The blue dashed lines represent the predictions of Eq. (15) with $\varphi/\pi = \delta = 1/3$.

The measured slope P is very close from the prediction $P = -2$ for anyons with an exchange phase $\varphi/\pi = \delta = 1/3$ (blue dashed line on Fig. 8A). The measured slopes slightly decreases in absolute value when T_S increases, varying from $P = -1.9$ for $T_S = 0.05$ to $P = -1.6$ at $T_S = 0.25$. In the opposite limit, $T_S \approx 1$ (empty blue circles on Fig. 8A), one observes a completely different behavior: the cross-correlations are completely suppressed in this case, $S_{34} = 0$, which corresponds to the fermionic behavior. $T_S \approx 1$ is reached for a complete pinch off of QPC1 and QPC2, which is the regime of strong backscattering corresponding to electron emission instead of anyon emission. One thus does not expect to observe manifestations of anyon statistics in this case, but rather fermionic antibunching ($S_{34} = 0$). This result can also be understood from a gauge invariance argument. By closing completely QPC1 and QPC2 ($T_S = 1$), one effectively implements a single QPC experiment which cannot provide information on the anyon statistics. The balanced configuration corresponds to applying equal voltages $V_1 = V_2$ at the two inputs of cQPC. These voltages can be removed by a gauge transformation shifting all the potentials by the value $V_1 = V_2$, thereby removing the sources from the QPC inputs. Note that this gauge argument does not hold anymore as soon as T_S deviates from $T_S = 1$, as removing the voltage V_i from one input of QPCi would result in applying the voltage $-V_i$ to its other input.

Fig. 8B presents the measurement of the normalized auto-correlations $(S_{33} + S_{44})/(4e^*T(1 - T))$. The data for $T_S = 1$ shows zero noise: as there is no random emission of anyons for $T_S = 1$, the input currents I_1 and I_2 are noiseless. For the smaller values of $T_S = 0.25$, $T_S = 0.15$ and $T_S = 0.05$, one observes an increasing noise when T_S decreases, corresponding to more and more dilute beams of anyons. This qualitative behavior is similar to the electron case at filling factor $\nu = 3$. However, contrary to the electron case, the value of the auto-correlation is larger but comparable with the value of the cross-correlations. One can also see that, contrary to the electron case, the noise data is systematically above the predictions from the classical model for the auto-correlations (blue and cyan dashed lines on Fig. 8B). Predictions for the auto-correlations of the current fluctuations can be deduced from current conservation relations at cQPC: $I_1 + I_2 = I_3 + I_4$. This implies the following relation for the fluctuations: $S_{33} + S_{44} + 2S_{34} = S_{11} + S_{22}$, where $S_{11} + S_{22}$ is the noise generated by QPC1 and QPC2 at the inputs of cQPC: $S_{11} + S_{22} = 2e^*(1 - T_S)I_+$. The normalized auto-correlations are thus predicted to be given by:

$$\frac{S_{33} + S_{44}}{4e^*T(1 - T)} = -\frac{S_{34}}{2e^*T(1 - T)} + \frac{(1 - T_S)I_+}{2T(1 - T)} = -PI_+ + \frac{(1 - T_S)I_+}{2T(1 - T)} \quad (14)$$

In the Poissonian limit $T_S \ll 1$, the prediction from the anyon model is $P(I_- = 0) = -2$ compared to $P_{cl}(I_- = 0) = 0$ in the fermion case. It leads to the following prediction for the ratio of the slopes $P_{auto}/P_{cl, auto} = 1 + 2|P(I_- = 0)|T(1 - T) > 1$. The larger noise compared to the classical model is thus another manifestation of the anyon tunneling mechanisms $W_{1 \rightarrow 2}$ and $W_{2 \rightarrow 1}$ that lead both to strongly negative cross-correlations, and to an increase of the auto-correlation noise compared to the classical predictions. At the quantitative level, for $T \approx 0.3$ (used in the experiment), one expects an increase of 80% of the noise compared to a measured increase of 50%. However, it is not surprising that the determination of P from the auto-correlation noise is not as accurate as its determination from cross-correlation measurements as it is obscured by the larger contribution of the input noise generated by QPC1 and QPC2 in the balanced configuration (second term of Eq. 14).

Fig. 8C presents the robustness of the measurements of P extracted from the normalized cross-correlations when varying the transmission T of cQPC. The measurements are performed in the range $0.18 \leq T \leq 0.47$, for which anyon tunneling (with fractional charge $e^* = e/3$) occurs at cQPC. As can be seen in the figure, all the measured data agree nicely with the prediction $P = -2$ with a small scatter of ± 0.15 around the expected value in the full range of transmissions T .

The agreement of the measured value of P with the prediction for $\varphi/\pi = \delta = 1/3$ shows that the measured values of φ and δ agree with the values in the bulk. However, it is known that experiments investigating anyon tunneling in single QPC devices fail to observe the expected nonlinearities of the I-V characteristics, that are predicted to be related to the scaling dimension δ (Wen, 1991; Fendley et al., 1995). In the weak backscattering regime, the backscattering probability is expected to decrease down to zero with a characteristic power law dependence, $T \propto V^{2\delta-2}$, where V is the bias voltage across the QPC. In contrast with the expected behavior, experiments show a saturation of T at large voltage to a constant value, or offset, that is different from 0. Subtracting this offset, several experiments have observed a quantitative agreement with predictions for the dependence of T with the applied voltage. For example, in the $\nu = 5/2$ case, by fitting the experimental data (after removal of the offset) with the $T(V)$ dependence predicted by the model, several works (Radu et al., 2008; Lin et al., 2012; Baer et al., 2014; Fu et al., 2016) have been able to extract the anyon fractional charge e^* and the tunneling exponent δ , and to use these values to discriminate between different possible topological orders of the $\nu = 5/2$ state.

Eq. (10) shows that the quantum models of anyon collisions (Rosenow et al., 2016; Lee and Sim, 2022) also predict power laws for the evolution of the tunneling current. They differ from the nonlinear behavior predicted in single QPC experiments (in particular in collision experiments, T evolves nonlinearly with the input anyon current I_+ , instead of the voltage V in single QPC experiments). However, they share common features, with T predicted to decrease down to zero at large current I_+ with a power law of the same exponent $2\delta - 2$. Interestingly, the exact dependence of T with I_+ is richer than the power law, as it depends on all the collision parameters e^* , φ , and δ (Ruelle et al., 2022):

$$T = \beta f(\delta, \xi_+) \quad (15)$$

$$f(\delta, \xi_+) = \frac{\Gamma(\delta + \xi_+)}{\Gamma(1 - \delta + \xi_+)} [\Psi(1 - \delta + \xi_+) - \Psi(\delta + \xi_+)] \quad (16)$$

$$\xi_+ = \frac{\hbar I_+}{2\pi e^* k_B T_{el}} [1 - \cos(2\varphi)] \quad (17)$$

where Γ and Ψ are the gamma and digamma functions (with $\Psi(x) = \Gamma'(x)/\Gamma(x)$), and β is a constant which does not depend on I_+ .

Fig. 8D shows the measurements of $T(I_+)$ in the balanced configuration of the collider. As shown in the figure, the data shows the expected decrease of T with I_+ . However, as observed in single QPC experiments, T saturates at large currents at an offset value. Following the analysis performed in single QPC experiments (Roddaro et al., 2003, 2004; Radu et al., 2008; Lin et al., 2012; Baer et al., 2014; Fu et al., 2016), the experimental data can be compared with Eq. (15) subtracting an offset value T_0 . The offset is extracted from a fit of the experimental data by a power law, $T(I_+) = T_0 + \alpha I_+^\gamma$, where T_0 , γ and α are the three fit parameters. Eq. (15) is also only valid for currents larger than the thermal limit ($I_+/e^* \geq k_B T_{el}/h$); therefore it cannot capture the thermal rounding observed on the experimental curves for $|I_+| \leq 35$ pA. In order to take into account these thermal effects, an offset of 35 pA is added to the values of I_+ in Eq. (15) (the same offset on I_+ is used on all the traces). Finally, the values of all the other parameters in Eq. (15) are fixed, with $\varphi/\pi = \delta = 1/3$, $T_{el} = 30$ mK, and $\beta = T(I_+ = 0)/f(\delta, \xi_+ = 0)$. The blue dashed lines on the figure represent the result of this analysis. As can be seen in Fig. 8D, the agreement with the data is excellent. Importantly, the data reproduces nicely the expected dependence on ξ_+ without adjusting parameter, taking into account braiding effects via the factor $(1 - \cos 2\varphi)$ in Eq. (17).

We finally discuss the results of anyon collisions in the unbalanced case ($I_- \neq 0$) at filling factor $\nu = 1/3$. As can be seen in Fig. 9, one observes a clear increase of P in absolute value when one increases the imbalance I_-/I_+ . This is in agreement with the discussion developed in the previous section. As braiding effects occur with opposite signs for the two sources, they decrease when moving from the unbalanced case ($I_- = I_+$) to the balanced one ($I_- = 0$). As a result, and contrary to a naive expectation, the effects of braiding are quantitatively more important when a single anyon source is plugged at the input of the collider. Data points at the lowest transmission ($T_S = 0.05$) agree very well with the predictions for $P(I_-/I_+)$ of Rosenow et al. (2016) taking $\varphi/\pi = \delta = 1/3$ (blue line).

The results are completely different in the strong backscattering regime, $T_S \approx 1$ (empty blue circles), where anyon emission is suppressed. As discussed before, $P = 0$ in the balanced case, $I_- = 0$. For $T_S = 1$ in the unbalanced case, $I_- \neq 0$, as already discussed in Section “Random collisions of electrons” in the electron case, this configuration is identical to a single QPC experiment. The noise then equals the random partition noise generated by the current difference between the inputs I_- and one has $P_{1QPC}(I_-/I_+) = -I_-/I_+$ independently of the statistics of the particles, fermions or anyons. Indeed for $T_S \approx 1$, the results are identical for anyons at $\nu = 1/3$ (open blue circle) and for fermions at $\nu = 3$ (open red circles) with $P(I_- = I_+) \approx -1$. This confirms that single QPC experiments only probe the charge of the particles and not their statistics.

Finally, one can notice that $|P(I_-/I_+)|$ decreases when one increases the emission probability T_S . This contrasts with the electron case that shows the opposite behavior. This spectacularly illustrates the difference between fermions, with trivial braiding phase $e^{i2\varphi} = 1$, and which are very well described by the classical model of collisions, and the anyon case, with $e^{i2\varphi} \neq 1$, for which braiding mechanisms lead to a value of P that is predicted not to depend on T_S (in the limit where $T_S \ll 1$). This opposite dependence in the emission probability T_S is a signature of braiding mechanisms in anyon collisions compared to the electron case. As shown in Fig. 9, the measured values of P do depend on T_S in the anyon case ($|P|$ decreases when T_S increases). This evolution, which is not captured by the model, is expected as one deviates from the Poissonian emission regime, and one expects to reach $P = -1$ for $T_S = 1$. However, no theoretical prediction is available at this time to capture the evolution of P with T_S .

Discussion of the results

The results of anyon collisions at the filling factor $\nu = 1/3$ presented in this article have been reproduced recently in three different experiments (Lee et al., 2022; Glidic et al., 2022; Ruelle et al., 2022). Glidic et al. (2022) and Ruelle et al. (2022) carried a similar analysis as the one presented here, by measuring the cross-correlations of the current fluctuations at the output of the collider and by studying the evolution of P with the imbalance I_-/I_+ between the collider inputs. Their results at $\nu = 1/3$ reproduce those presented

Fig. 9 Measurements of $P(I_-/I_+)$ for filling factors $\nu = 1/3$ (blue points) and $\nu = 3$ (orange points). The blue line represents predictions from Rosenow et al. (2016) with $\varphi/\pi = \delta = 1/3$. The black dashed line is the prediction for the single QPC experiment, $P_{1QPC}(I_-/I_+) = -I_-/I_+$. In the unbalanced case the anyon ($\nu = 1/3$) and fermion ($\nu = 3$) cases show opposite behaviors. $|P(I_- = I_+)|$ increases when T_S decreases in the anyon case whereas $|P(I_- = I_+)|$ decreases when T_S decreases in the fermion case.

Fig. 10 (A) Sketch of the anyon collider device for the measurement of T and $\tilde{T}$ in the balanced configuration. For the measurement of T one applies a small a.c. bias δV_1 to contact 1 and one measures $T = \delta I_4 / (T_1 \delta I_1^0)$. For the measurement of $\tilde{T}$, the small a.c. bias is applied to contact 7 and one measures $\tilde{T} = \delta I_4 / ((1 - T_1) \delta I_1^0)$. (B) Measurements of $T(I_+)$ and $\tilde{T}(I_+)$ for two different settings of cQPC.

here. Lee et al. (2022) focused on the completely unbalanced case, $I_- = I_+$, by switching off source 2 ($I_2 = 0$), and carried a different analysis by measuring the auto-correlations of the current fluctuations at output 4 of the collider, S_{44} , as a function of the tunneling current across cQPC I_T . Comparing the data with the predictions of the quantum model for the Fano factor F , Eq. (13), Lee et al. (2022) show a very nice agreement with $F = +3.27$, which is the prediction from the quantum model of anyon collisions for $\varphi/\pi = \delta = 1/3$ (whereas the classical model predicts $F_{cl} = 1$, see Eq. (5)). All these experiments thus confirm the observation of fractional statistics at $\nu = 1/3$.

However, an open question remains regarding the measured dependence of the backscattering probability of cQPC T with the total anyon current I_+ . First, as discussed in Section “The anyon collider: Experimental results,” the measured evolution of $T(I_+)$ does not reproduce the predictions for its nonlinear behavior, even though a good agreement can be obtained when taking into account a possible offset of the transmission. More importantly, as originally discussed in Lee and Sim (2022), the measured value of T should show a dependence on the experimental configuration used for the measurement. T is defined as $\partial_{I_-} I_T|_{I_-=0}$. It is measured in the balanced configuration by generating a small a.c. current δI_1 at input 1 of cQPC and by measuring the resulting tunneling current δI_T in output 4, $T = \delta I_T / \delta I_1$. In configuration 1 (see Fig. 10A), which leads to the predictions of Eq. (15), the current δI_1 is an anyon current generated by a small a.c. voltage δV_1 applied to contact 1, $\delta I_1 = T_1 \delta I_1^0$, with $\delta I_1^0 = G_0/3\delta V_1$. In the second configuration (see Fig. 10A), a small a.c. current δI_7^0 is injected from contact 7, with $\delta I_1 = (1 - T_1) \delta I_7^0$. δI_1 thus mostly consist of a direct propagation of charge from contact 7 to cQPC and not of anyons tunneling at QPC1. The backscattering transmission $\tilde{T}$ measured in this second configuration is given by $\tilde{T} = \delta I_T / ((1 - T_1) \delta I_7^0)$. As predicted in Lee and Sim (2022), this should lead to a ratio $T/\tilde{T} = \sin(2\varphi)/(2\pi e^*/e) < 1$. A difference between T and $\tilde{T}$ is indeed observed (Ruelle et al., 2022), see Fig. 10B, with $T < \tilde{T}$. However, the measured ratio of 0.85 is much larger than the prediction of $\sin(2\pi/3)/(2\pi/3) \approx 0.41$ for $\varphi = \pi/3$. This might be related to the observed saturation of both T and $\tilde{T}$ at large current I_+ that suppress the nonlinear dependence of T on I_+ . As discussed in Glidic et al. (2022) and Ruelle et al. (2022), as P is defined from the normalization of the cross-correlations by T , a remarkable quantitative agreement with predictions of the quantum model is obtained using one definition of T , but would not be obtained using $\tilde{T}$. It is thus important to also test the agreement between data and theory using quantities that do not rely on the definition of T . This is precisely the advantage of using the definition of the Fano factor F as the ratio of the noise of the tunneling current on the tunneling current flowing through cQPC in the collision experiment (with the inconvenient that F can only be used in the unbalanced configuration as $I_T = 0$ in the balanced case). Measurement performed in Lee et al. (2022) for $I_- = I_+$ agree also perfectly with the predictions from the quantum model of anyon collisions, $F \approx 3.27$ showing that this agreement is robust to different analysis and to different quantities used for the normalization of the noise.

Conclusion

We have presented and compared collision experiments for different particles with different statistics: bosons and fermions, that can be described by a classical collision model, and anyons, for which specific mechanisms related to anyon braiding need to be taken into account by a quantum model. Boson and fermion collisions are governed by two-particle bunching (in the bosonic case) and antibunching (in the fermionic case). They lead respectively to negative current cross-correlations due to the formation of charge

packets in a given output of the collider, or on the contrary to a suppression of the current cross-correlations when the two particles always exit in different outputs. Importantly, two-particle boson and fermion interferences are only present when one particle is emitted at each input of the collider, and are thus proportional to the emission probability squared: T_S^2 . In the anyon case, specific anyon tunneling mechanisms occur at the beam splitter, which are governed by the anyon braiding factor $e^{i2\varphi}$. As a result, when one anyon is emitted at a given input of the beam-splitter, backward anyon tunneling may occur, where another anyon bunches together with the one generated by the anyon source in a given output of the beam splitter, leaving a hole in the other output. As in the bosonic case, this bunching mechanism leads to negative current cross-correlations. However, contrary to the bosonic case, it is present even when a single anyon is emitted at a given input of the beam splitter (and no anyon is emitted at the other input). As a result, the cross-correlations are proportional to T_S contrary to T_S^2 in the bosonic case (and in the fermionic one), providing a clear way to distinguish anyons from bosons (and fermions).

Regarding the quantitative analysis of anyon collisions, the explicit dependence of the anyon tunneling rates with the anyon braiding phase provides a way to directly measure the anyon fractional exchange phase φ . Different analysis can be performed by defining a Fano factor from the normalization of the noise, either by the incoming anyon current multiplied by the anyon backscattering probability at the beam splitter, TI_+ , or by the tunneling current at the beam splitter I_T . Both analyses provide an excellent agreement with the predictions using $\varphi = \pi/3$, which is the expected exchange phase for anyons at the filling factor $\nu = 1/3$. However, the robustness of the measured values of P with respect to the definition of the transmission T remains to be understood.

Anyon colliders can also be used to probe other varieties of anyons with different statistics obtained by varying the filling factor ν . In particular, experiments carried at the filling factor $\nu = 2/5$ (Ruelle et al., 2022; Glidic et al., 2022) on anyons with a fractional charge $e^* = e/5$ have demonstrated the ability of the anyon collider to distinguish between anyons of different statistics. Indeed, both experiments measure a smaller Fano factor $P(I_- = 0) \approx -0.6 \pm 0.1$ in Ruelle et al. (2022) (for the lowest value of T_S) and $P(I_- = 0) \approx -0.97 \pm 0.15$ in Glidic et al. (2022). Note that a large part of the difference between the two measured values of P may be understood from different normalizations. The normalization presented in this manuscript is used in Ruelle et al. (2022), $P = S_{34}/(2e^*T(1 - T)I_+)$, whereas P is defined as $S_{34}/(2e^*T(1 - T)(1 - T_S)I_+)$ in Glidic et al. (2022). The additional factor $1 - T_S$ may lead to nonnegligible differences (with an increase of P compared to the other definition) when T_S is not much smaller than one. Interestingly, both these values are close to the prediction for P for an exchange phase $\varphi = \pi/5$ which does not correspond to the simplest descriptions of anyons at filling factor $\nu = 2/5$ (but rather to the $\nu = 1/5$ case). Contrary to $\nu = 1/3$, where the edge structure is simple, $\nu = 2/5$ is also an example of a fractional quantum Hall state with a complex edge structure, with two copropagating edge channels. In this situation, one might expect that interchannel Coulomb interaction plays a role (Idrisov et al., 2022), for example, through the formation of charge and neutral eigenmodes. It will be important to characterize such interaction effects for fractional quantum Hall states with complex edge structure. It will be particularly relevant when investigating non-abelian anyons at the filling factor $\nu = 5/2$, where several copropagating channels are present. In this context, it is important to point that recent theory works have predicted the possibility to characterize non-abelian phases using the anyon collider, and to distinguish between different non-abelian topological orders (Lee and Sim, 2022).

Anyon collisions can also be extended to the time or frequency domains. In the first case, one can implement the anyon version of the Hong-Ou-Mandel experiment (Hong et al., 1987; Bocquillon et al., 2013) presented in Section “Fermion and boson collisions.” In the anyon case (Rech et al., 2017; Jonckheere et al., 2022), one triggers the emission of pulses carrying a fractional charge and measures the variations of the current cross-correlations between the currents at the output of the beam splitter as a function of the time delay between the two sources. In the frequency domain, one generates a stationary flow of anyons, but measures the current cross-correlations at high frequency (instead of low frequency in the present experiment). It has already been shown that anyon properties could be directly measured from characteristic time or frequency scales, such as their fractional charge via the measurement of the Josephson frequency $f_J = e^*V/h$ (Ferraro et al., 2014; Roussel et al., 2016; Kapfer et al., 2019; Bisognin et al., 2019). Implementing similar experimental methods in the anyon collider geometry would provide direct measurements of anyon fractional statistics (Safi, 2020; Jonckheere et al., 2022), with a simplified analysis that would not rely on the simultaneous measurement of the backscattering transmission T or the tunneling current I_T at the central beam splitter, but rather directly from a characteristic time or frequency scale.

Abstract

A general formalism, dubbed “Gauge Theory of States/Phases of Matter,” which serves to partially classify electronic states in systems of condensed matter physics, and the theory of fractional statistics in low-dimensional systems are reviewed. Applications to the quantum Hall effect, to 2D time-reversal invariant insulators, and to certain 2D wave guides with chiral edge modes are sketched. The theory of 3D topological insulators, including Halperin’s 3D quantized Hall effect and axionic insulators, is discussed too. The chiral magnetic effect is recalled and applied to Weyl semimetals.

Key points

- To begin with, the so-called gauge theory of states/phases of matter is reviewed. This theory is a very useful tool in the study of systems of condensed matter without local order parameters so that Landau theory is not applicable.
- Concepts and facts from quantum field theory and, in particular, gauge theory are recalled. Some basic facts concerning the chiral anomaly are summarized. As a first application, conductance quantization in quantum wires is reviewed.
- The general theory of fractional (braid-group) statistics in one-dimensional and planar quantum systems is outlined.
- General features of the quantum Hall effect are summarized. The presence of anomalous chiral edge currents in planar incompressible electron gases (Hall fluids) is derived from general principles. It is shown that bulk transport properties of Hall fluids can be derived from Chern–Simons theory. A general classification of “abelian” Hall fluids is presented.
- A duality between insulators and superconductors and between Hall fluids and chiral photonic wave guides is recalled and applied.
- A general description of time-reversal invariant planar topological insulators realized in certain electron gases with spin–orbit interactions is presented.
- The so-called chiral magnetic effect is derived from explicit formulae for anomalous commutators. A five-dimensional analog of the quantum Hall effect is described and used to derive the basic equations of axion electrodynamics. These equations yield a generalization of the chiral magnetic effect useful in condensed matter physics and cosmology.

- Three-dimensional topological insulators are considered. Halperin's 3D (quantum) Hall effect is derived from axion electrodynamics. The generalized chiral magnetic effect is applied to derive a formula for the conductivity of Weyl semi-metals in the presence of a magnetic field.
- Some general conclusions and remarks on what is missing in this review are offered.

Introduction: Gauge theory of states of matter

This contribution is a gently altered and expanded version (with minor corrections implemented) of a review paper Fröhlich (2023) on the same subject that has appeared in the Journal of Mathematical Physics.¹

Fröhlich (2023) includes material that was previously reviewed in Fröhlich and Studer (1993), Fröhlich et al. (1996), and Fröhlich (2018), and references given there. In particular, Fig. 2 first appeared in print in Fröhlich (2018), and Fig. 3 first appeared in Fröhlich et al. (1996). Both figures had previously been used on slides of lectures of mine. Besides showing substantial overlap with Fröhlich (2023) and with the present review, reference Fröhlich et al. (1996) contains quite a lot of material that is complementary to the one covered in the following. It is recommended to the attention of the reader.

This article is a survey of various developments in theoretical condensed matter physics, including ones that may not be generally known and appreciated yet. Many of the methods underlying the results discussed in the following and the style of this contribution are influenced by trends in particle physics and mathematical physics. This may make its reading somewhat challenging for readers not familiar with these fields. However, I am convinced that interactions between different fields of physics have always been fruitful and are likely to trigger interesting developments that would be missed without such interactions.

Some of the work on mathematical aspects of condensed matter physics carried out by my collaborators and myself during the period from the late 1980s until the late nineties of the past century (see Fröhlich and Studer, 1993; Fröhlich et al., 1996; Fröhlich, 2018), as well as a sketch of the theory of fractional- or braid statistics (see Klaiber, 1968; Streater and Wilde, 1970; Fröhlich, 1976, 1978; Fröhlich and Marchetti, 1988; Fröhlich and Gabbiani, 1990), which is relevant for understanding various features of condensed matter physics in two dimensions, form the core of this contribution. The findings described in Fröhlich and Studer (1993), Fröhlich and Marchetti (1988), and Fröhlich and Gabbiani (1990) have led to a general formalism, dubbed "*Gauge Theory of States/Phases of Matter*," that has turned out to be very useful in characterizing properties of electron gases in a variety of systems of condensed matter physics, among them "*topological insulators*." This formalism complements the *Landau theory* of phases and phase transitions. For ideas and results somewhat related to those in Fröhlich and Studer (1993) and Fröhlich et al. (1996) see Hasan and Kane (2010a), Qi and Zhang (2011), Hasan and Moore (2011), and Sachdev (2019), and references given there.

One of the insights at the root of the efforts in Fröhlich and Kerler (1991), Fröhlich and Zee (1991), Fröhlich and Thiran (1994), Fröhlich (1995), Alekseev et al. (1998), and Fröhlich and Pedrini (2000), reviewed in (Fröhlich and Studer, 1993), Fröhlich et al. (1996), and Fröhlich (2018), was the realization that the *chiral anomaly*, discovered by particle theorists (see Jackiw et al. (1986) and references given there) can be used to predict the existence of chiral edge currents in two-dimensional interacting electron gases exhibiting the quantum Hall effect, and that these edge currents can be described using results from the theory of current (Kac–Moody) algebras; see Fröhlich and Kerler (1991). For the integer Hall effect observed in two-dimensional systems of noninteracting electrons in an external magnetic field, the existence of chiral edge currents had earlier been predicted by B. Halperin in a celebrated paper (Halperin, 1982). (See also Fröhlich et al. (2000) for some mathematical results on edge currents in noninteracting electron gases.) Independently of our efforts, the use of the chiral anomaly for the purpose of a general analysis of chiral edge currents in two-dimensional electron gases exhibiting the quantum Hall effect, including interacting gases, was advocated by Wen (1990) and Blok and Wen (1990).

The realization that the theory of fractional (braid) statistics may be put to use in analyses of the fractional quantum Hall effect was inspired by Laughlin's famous work (Laughlin, 1983a, b). The importance of this novel form of quantum statistics in the study of various systems of two-dimensional condensed matter physics may justify the inclusion of a brief outline of the theory of braid statistics in Section "*What is fractional or braid statistics?*" of this contribution. Applications to the theory of the fractional quantum Hall effect are sketched in Section "*The 2D quantum Hall effect*."

Numerous comments placing ideas presented in the following into a wider context, as well as plenty of references can be found in subsequent sections (but see also Fröhlich, 2023; Fröhlich and Studer, 1993; Fröhlich et al., 1996; Fröhlich, 2018). The subject covered in this contribution owes its advancement and its successes to the efforts of many colleagues. Some of their work will be referred to or is quoted in papers referred to in the text that follows. I wish to offer my apologies to colleagues whose contributions may not be properly highlighted in the following, due to my lack of knowledge of their work or oversights, or because their contributions are too recent to be included in this presentation. Results concerning topologically protected states of systems of *noninteracting* electron gases started with work of Laughlin (1981) and of Thouless et al. (1982) and Kohmoto (1985) and continued with Avron et al. (1990) and Avron et al. (1994). It cannot be reviewed in what follows; but see Kane and Mele

¹I wish to thank AIP publishing for granting me the right to reproduce major portions of Fröhlich (2023) in this article.

(2005), Fu and Kane (2007), Kitaev (2009), Hasan and Kane (2010b), Graf and Porta (2013), Gawedzki (2015), Schulz-Baldes (2016), and Kennedy and Zimbauer (2016) for plenty of references to more recent, important work in this direction.²

The analysis presented in this review is not meant to be mathematically rigorous, although the arguments described in the text or in the papers on which it is based are quite carefully constructed and, I think, convincing. It is hoped that this contribution may help its readers understand the relevance and usefulness of the *Gauge Theory of States/Phases of Matter* and of the theory of *fractional (braid) statistics* in various studies of condensed matter physics.

Here is a brief summary of the goals and the contents of this paper.

- In this introductory section, I will describe some basic concepts and results from gauge theory, current algebra, and general relativity, with the purpose to introduce the following important ingredients of the *Gauge Theory of States/Phases of Matter*.
 1. *Effective Actions* = generating functionals of connected current Green functions $\Leftrightarrow$ formulae for transport coefficients, in particular *conductivities*.
 2. Implications of *gauge invariance* ($\Leftrightarrow$ current conservation, Ward–Takahashi identities), *locality*, and *power counting* (i.e., arranging different terms in an action functional according to their scaling dimensions) on the form of *Effective Actions*.
 3. *Gauge anomalies* and their cancellations (anomaly inflow) $\Leftrightarrow$ cooperation between bulk- and edge/surface degrees of freedom $\Leftrightarrow$ “holography.”

The *Gauge Theory of States of Matter* takes the place of *Landau Theory* when the latter is not applicable, for example, because there are no local order parameters available to characterize physical states of a certain system of condensed matter of interest. The *Gauge Theory of States of Matter* yields information on current Green functions, whence on transport coefficients (conductivities), which, thanks to *Kubo formulae*, can be expressed as integrals over certain current Green functions.

Remark.

- (i) A system of condensed matter physics with a *local order parameter* is one whose phase diagram can be described with the help of an order-parameter field, $\varphi(x)$, where x is a point in physical space. This field is most often a scalar or pseudo-scalar field with $N = 1, 2, \dots$ components, whose expectation value, $\langle \varphi(x) \rangle_\xi$, in a ground state or equilibrium state $\langle (\cdot) \rangle_\xi$ corresponding to a pure phase labeled by ξ *uniquely* identifies this phase, and whose correlators (Green functions) in such states enable one to study physically interesting fluctuations in the system at large distance scales and low energies. The systems studied in this paper do *not* have local order parameters (in this sense of the expression). We will attempt to describe their ground states and equilibrium states by coupling their degrees of freedom to real or fictional external gauge fields. Special attention will be paid to “*topological insulators*,” which—it will turn out—can be described by *topological* gauge field theories, such as Chern–Simons theories and generalizations thereof. Some authors, see, for example, Wen, 1990; Blok and Wen, 1990, then speak of “topological order,” a somewhat fuzzy notion.
- (ii) I should mention that a “change of perspective” has recently been initiated in Gaiotto et al. (2015) and reviewed in McGreevy (2022) (and references given there) based on developing the idea of “higher-differential-form symmetry,” which enables one to assign conserved charges to certain extended objects. With such generalizations of the concept of symmetry it appears to become possible to characterize most known equilibrium phases of matter by using an extended version of Landau theory derived from such generalized symmetries. I am not sufficiently knowledgeable to say much about the attempts alluded to here. But I tend to think that, when compared to the formalism described in this paper, the new perspective amounts mostly to a change of language.

- In Section “*The chiral anomaly*,” I summarize some basic facts concerning the *chiral anomaly*. I will then sketch the derivation of the chiral anomaly in 2D theories of massless fermions making use of bosonization. As an application, conductance quantization in quantum wires will be discussed.
- Section “*What is fractional or braid statistics?*” is devoted to a summary of results concerning *fractional (braid) statistics*. These results are connected in a natural way to the material in Section “*The chiral anomaly*” and are relevant for the material reviewed in Section “*The 2D quantum Hall effect*” (quantum Hall effect).
- In Sections “*The 2D quantum Hall effect*,” “*Induced Chern–Simons actions, dualities, and 2D chiral photonic wave guides*,” and “*Chiral spin currents in planar topological insulators*,” I present various applications of the Gauge Theory of States of Matter to the characterization and classification of “topologically protected” correlated *bulk- and surface states of interacting systems* of condensed matter in two dimensions, in particular of 2D electron gases/liquids, which do not have local order parameters. Among such applications, I will consider the following ones³:
 1. Theory of the Fractional Quantum Hall Effect (Section “*The 2D quantum Hall effect*”)
 2. Theory of chiral states of light in certain planar wave guides (Section “*Induced Chern–Simons actions, dualities, and 2D chiral photonic wave guides*”)
 3. Time-reversal invariant planar “topological” insulators and their chiral-edge spin currents (Section “*Chiral spin currents in planar topological insulators*”)

²For lack of expertise, I will not be able to review any very recent results on topological states of matter.

³A fairly extensive list of references to relevant work will be given later in the text.

- In Section “Anomalous current commutators and the chiral magnetic effect,” I sketch the derivation of the *chiral magnetic effect*. Some consequences of this effect in condensed matter physics are described in later sections.
- Subsequently, in Sections “A five-dimensional cousin of the Hall effect and axion electrodynamics” and “3D Topological insulators and ‘axions,’” I discuss higher-dimensional cousins of the Quantum Hall Effect,⁴ 3D topological insulators, and so called *Weyl semimetals* exhibiting the chiral magnetic effect.⁵ Applications of related ideas and methods in other areas of physics, in particular in cosmology, should also, yet cannot be discussed in this paper; but see Alekseev et al. (1998), Fröhlich and Pedrini (2000), Boyarski et al. (2012), Brandenburg et al. (2017), and Schober et al. (2018).

Effective actions and their properties

In the remainder of this introduction, I explain how, under suitable assumptions, the general form of effective gauge-field actions, that is, generating functionals of connected current Green functions, can be determined, and I elucidate their properties and uses. My discussion follows the one in Fröhlich et al. (1996). Readers who may find it a little too abstract are encouraged to proceed to Section “A first application: Conduction quantization in quantum wires” and then to Section “The 2D quantum Hall effect.”

We consider a quantum-mechanical system whose matter degrees of freedom are described by fields $\bar{\psi}, \psi, \dots$ over a space-time region, Λ , equipped with a metric, $g_{\mu\nu}$, of signature $(-1, 1, 1, 1)$. The dynamics of the system is assumed to be derivable from an action functional

$$S(\bar{\psi}, \psi, \dots; g_{\mu\nu}, A_\mu), \quad (1)$$

where $A = (A_\mu)$ is the electromagnetic vector potential describing an external electromagnetic field (or some other gauge potential describing an external gauge field) acting on the system. We assume that there is a conserved vector current (density) J^μ , with $\partial_\mu J^\mu = 0$. If the current J^μ is charged, that is, is carried by electrically charged degrees of freedom, then these degrees of freedom interact with the electromagnetic field. In the action functional (1) of the system, the charged fields are coupled to the electromagnetic field by “minimal substitution,” that is, by replacing derivatives by covariant derivatives.

The *Effective Action* of the system at zero temperature on a space-time region Λ with metric $g_{\mu\nu}$ in an external electromagnetic field with vector potential A_μ can then be constructed with the help of, for example, functional integral methods.⁶ We consider the formal functional integral

$$S_{\text{eff}}(g_{\mu\nu}, A_\mu) := -i\hbar \ln \left(\int \mathcal{D}\bar{\psi} \mathcal{D}\psi \exp \left[\frac{i}{\hbar} S(\bar{\psi}, \psi, \dots; g_{\mu\nu}, A_\mu) \right] \right) + (\text{divergent}) \text{ const.} \quad (2)$$

A precise definition of the right side in (2) involves imposing “boundary conditions,” initial and final field configurations, on the functional integral, for example, ones corresponding to ground states of the system (and renormalizing divergences when short-distance regularizations are removed). But in this review I will not present technical details concerning the precise definition of S_{eff} and the choice of boundary conditions in (2).

Next, I review some well-known, important *properties of effective actions*.

1. The variational derivatives of S_{eff} with respect to A_μ are given by connected current Green functions:

$$\frac{\delta S_{\text{eff}}(g_{\mu\nu}, A_\mu)}{\delta A_\mu(x)} = \langle J^\mu(x) \rangle_{g, A}, \quad (3)$$

and

$$\frac{\delta^2 S_{\text{eff}}(g_{\mu\nu}, A_\mu)}{\delta A_\mu(x) \delta A_\nu(y)} = \langle J^\mu(x) J^\nu(y) \rangle_{g, A}^c \quad \text{for } x \neq y, \quad (4)$$

where $\langle (\cdot) \rangle_{g, A}$ denotes a time-ordered expectation in the presence of external fields $g_{\mu\nu}$ and A_μ . Formally this follows from Eq. (2).

2. We consider the effect of a gauge transformation, $A_\mu \mapsto A_\mu + \partial_\mu \chi$, where χ is an arbitrary smooth function on Λ , on the effective action S_{eff} . Using (3) one finds that

$$\frac{\delta S_{\text{eff}}(g_{\mu\nu}, A_\mu + \partial_\mu \chi)}{\delta \chi(x)} = \partial_\mu \langle J^\mu(x) \rangle_{g, A} = 0 \quad (5)$$

vanishes, because J^μ is conserved. Thus, S_{eff} is *invariant under gauge transformations*.

3. We may also vary S_{eff} with respect to the metric $g_{\mu\nu}$:

⁴See Fröhlich and Pedrini (2000), Boyarski et al. (2012), Brandenburg et al. (2017), and Schober et al. (2018); they were later applied to studies in cold-atom physics—see Price et al. (2015) and Lohse et al. (2018) and references given there.

⁵An effect discovered in a preliminary form in Vilenkin (1980) and Fukushima (2013) and studied systematically in Alekseev et al. (1998).

⁶Functional- or path integral methods were originally introduced by Dirac (1933). An operator formalism to derive expressions for effective actions has been sketched elsewhere; see, e.g., Fröhlich and Kerler (1991); Fröhlich et al. (1996), and references given there.

$$\frac{\delta S_{\text{eff}}(g_{\mu\nu}, A_\mu)}{\delta g_{\mu\nu}(x)} = \langle T^{\mu\nu}(x) \rangle_{g,A},$$

where $T^{\mu\nu}$ is the energy-momentum tensor of the system. Using local energy-momentum conservation, that is, $\nabla_\mu T^{\mu\nu} = 0$, we find that $S_{\text{eff}}(g_{\mu\nu}, A_\mu)$ is invariant under space-time coordinate transformations.

A general (possibly curved) metric $g_{\mu\nu}$ can be used to describe certain defects (disclinations) in a condensed matter system.

Invariance of S_{eff} under Weyl rescalings of the metric implies that $\langle T^\mu_\mu(x) \rangle_{g,A} \equiv 0 \leftrightarrow$ *scale-invariance* (criticality) of the system.

4. In our analysis of ground-state properties of insulators, it will be assumed that the external fields $g_{\mu\nu}$ and A_μ vary very slowly in space and time so that an adiabatic theorem can be invoked in the description of the time-dependence of the state of the system under consideration, and that the Hamiltonians exhibit a spectral (or mobility) gap above the ground-state energy at all times. One may then argue that the zero-temperature connected current Green functions of such a system have good decay properties in space and time. In the *scaling limit*, that is, in the limit of very large distances and very low frequencies, its effective action can then be expected to approach a functional that is a space-time integral of *local, gauge-invariant polynomials* in A_μ and derivatives of A_μ , as well as curvature quantities only depending on the metric $g_{\mu\nu}$. These terms can be organized according to their scaling dimensions (power counting—I recall that a gauge potential and a space-time derivative scale like an inverse length). Among these terms, there may be *topological* (metric-independent) action functionals that can be indicative of “topological protection” (or “topological order”) of the states in question.
5. A *generalization*: It is sometimes useful to consider more general effective actions involving *non-abelian gauge fields* and to analyze the associated currents, which are only covariantly conserved. Non-abelian gauge fields may represent physical external fields; but they may also represent “virtual” or “emergent” ones merely serving to develop the response theory needed to determine transport coefficients, such as conductivities, associated with the currents corresponding to those gauge fields. As an example of the relevance of non-abelian gauge fields in the study of condensed matter physics, I recall that, in nonrelativistic quantum theory, electron spin couples to $SU(2)$ -gauge fields describing Zeeman interactions,⁷ spin-orbit interactions and exchange interactions described by a *Weiss exchange field* (see Albert et al., 2006). The nonrelativistic quantum theory of electron gases/liquids turns out to be perfectly $U(1)_{\text{em}} \times SU(2)_{\text{spin}}$ -gauge invariant (see Anandan, 1989; Fröhlich and Studer, 1993; Fröhlich et al., 1996). This observation is not only conceptually interesting; it can be used to, for example, analyze states of *time-reversal invariant planar topological insulators* (see Fröhlich, 2018 and Section “Chiral spin currents in planar topological insulators”) and chiral spin liquids (see, e.g., Fröhlich et al., 1996).

It turns out that properties 1 through 5 enable us to determine the general form of bulk effective actions, S_{eff} , of (among other systems) *insulators* in the scaling limit and hence to derive formulae for transport coefficients, in particular certain conductivities, such as the Hall conductivity.

Example. We consider an insulator with broken parity (P) and time-reversal (T) symmetries confined to a region, Ω , of a flat 2D surface (e.g., an interface between an insulator and a semiconductor) embedded in physical space. The space-time of this system is defined to be $\Lambda = \Omega \times \mathbb{R}$. The effective action of the system can then be argued to tend to

$$S_{\text{eff}}(A) = \frac{\sigma_H}{2} \int_\Lambda A \wedge dA + \frac{1}{2} \int_\Lambda d^2x \, dt \, [\underline{E}(x) \cdot \varepsilon \underline{E}(x) - \mu^{-1} B(x)^2] + \dots,$$

as the scaling limit is approached, where σ_H is the Hall conductivity, ε is the tensor of dielectric constants, μ is the magnetic permeability, and the dots stand for further less relevant terms. In the first term on the right side, A is viewed as a differential 1-form, d denotes exterior differentiation of differential forms, and $\wedge$ is the exterior product of differential forms. We note that the first term on the right side, that is, the *Chern–Simons action*, is *not* gauge-invariant if the space-time region Λ has a nonempty boundary, $\partial\Lambda = \partial\Omega \times \mathbb{R}$. This deficiency is cured by a boundary action. The cooperation of the Chern–Simons action and the boundary action in preserving gauge invariance may be viewed as an example of “*holography*” (see Section “The 2D quantum Hall effect”).

The formalism sketched here can be generalized to become applicable to equilibrium states at positive temperature. For further details concerning the material reviewed here, see Fröhlich and Studer (1993), Fröhlich et al. (1996), and Fröhlich (2018).

The chiral anomaly

An excellent general reference for this section is Jackiw et al. (1986); (the original results can be found in Adler (1969) and Bell and Jackiw (1969), see also Fujikawa (1979, 1980)). We consider a system composed of relativistic, massless charged fermions in a (flat) space-time region, Λ , of dimension $2n$, $n = 1, 2, \dots$. The (operator-valued, quantum-mechanical) vector current of this system is denoted by J^μ and the axial-vector current by J^μ_5 . The vector current is conserved, that is,

$$\partial_\mu J^\mu = 0 \leftrightarrow \text{gauge invariance of theory.}$$

But the axial-vector current tends to be *anomalous*. In two space-time dimensions, for massless fermions,

⁷These are caused, for example, by an external magnetic field or by the vorticity of a velocity field that generates the motion of an ionic background.

$$\partial_\mu J_5^\mu = \frac{\alpha}{\pi} E, \quad \alpha := \frac{e^2}{\hbar}, \quad [J_5^0(\vec{y}, t), J^0(\vec{x}, t)] = -i \frac{\alpha}{\pi} \delta'(\vec{x} - \vec{y}), \quad (6)$$

where α is the finestructure constant and E is the external electric field.⁸

In four dimensions, for massless fermions,

$$\partial_\mu J_5^\mu = \frac{\alpha}{4\pi^2} \varepsilon^{\nu\lambda\kappa\rho} F_{\nu\lambda} F_{\kappa\rho} = \frac{\alpha}{2\pi^2} \vec{E} \cdot \vec{B}, \quad (7)$$

and

$$[J_5^0(\vec{y}, t), J^0(\vec{x}, t)] = i \frac{\alpha}{4\pi^2} \left(\vec{B}(\vec{y}, t) \cdot \vec{\nabla}_{\vec{y}} \right) \delta(\vec{x} - \vec{y}), \quad (8)$$

where $\vec{E}$ is the electric field and $\vec{B}$ is the magnetic induction.⁹ For massive fermions, there are terms proportional to fermion masses contributing to $\partial_\mu J_5^\mu$. The term $\vec{E} \cdot \vec{B}$ on the right side of (7), the “instanton density,” is dual to $\frac{1}{2} F \wedge F$ (where F is interpreted as a 2-form) and $F \wedge F$ is the exterior derivative of the Chern–Simons 3-form, which expresses the *helicity* of the electromagnetic field.

For later purposes we also introduce the left and right chiral currents

$$J_\ell^\mu := \frac{1}{2} [J^\mu + J_5^\mu], \quad J_r^\mu := \frac{1}{2} [J^\mu - J_5^\mu]. \quad (9)$$

The commutation relations in (6) and (8) then imply that

$$\begin{aligned} [J_{\ell/r}^0(\vec{y}, t), J^0(\vec{x}, t)] &= \pm i \frac{\alpha}{2\pi} \delta'(\vec{x} - \vec{y}), & \text{in } d = 2, \\ [J_{\ell/r}^0(\vec{y}, t), J^0(\vec{x}, t)] &= \pm i \frac{\alpha}{8\pi^2} \left(\vec{B}(\vec{y}, t) \cdot \vec{\nabla}_{\vec{y}} \right) \delta(\vec{x} - \vec{y}), & \text{in } d = 4. \end{aligned} \quad (10)$$

Remark. It is sometimes of interest to study systems of matter in a noninertially moving background—for example, electrons in a rotating metallic cylinder, a Bose gas in a rotating trap, or the Earth’s atmosphere or oceans. Suppose the motion of the background is generated by a (possibly time-dependent) velocity field, $\vec{V}$, on physical space. Studying the matter currents of such a system, one finds that there is an anomalous axial vector current satisfying an inhomogeneous continuity equation analogous to (7) and exhibiting anomalous commutators analogous to (8), but with $M\vec{V}$ playing the role of $e\vec{A}$, hence $M\vec{\omega}$ playing the role of $e\vec{B}$, where M is a mass scale and $\vec{\omega} = \vec{\nabla} \times \vec{V}$ is the vorticity of the velocity field $\vec{V}$.¹⁰ Effects observed in systems embedded in a moving background have been described in Fröhlich and Studer (1993) and Fröhlich et al. (1996). Some of them will be mentioned in Sections “The 2D quantum Hall effect” and “Anomalous current commutators and the chiral magnetic effect.”

As a service to the reader we derive the formulae in (6), (setting $\hbar = 1$). We consider a system of massless fermions on 2D Minkowski space, Λ . Let ι be the 1-form dual to the vector current density J^μ . Then

$$\partial_\mu J^\mu = 0 \quad \Leftrightarrow \quad d\iota = 0.$$

Poincaré’s lemma then implies that

$$\iota = \frac{Q}{\sqrt{2\pi}} d\varphi, \quad \text{where } \varphi \text{ is a pseudo – scalar field}$$

and Q is a quantity with the dimension of charge. Thus

$$J^\mu = \frac{Q}{\sqrt{2\pi}} \varepsilon^{\mu\nu} \partial_\nu \varphi \quad (11)$$

In two space-time dimensions (using the metric $g_{\mu\nu}$ to raise and lower indices), the axial-vector current of a system of massless Dirac fermions is given by

$$J_5^\mu = \varepsilon^{\mu\nu} J_\nu \stackrel{(11)}{=} \frac{Q}{\sqrt{2\pi}} \partial^\mu \varphi, \quad (12)$$

see Schwinger (1962) and Gatttringer and Seiler (1994).

It is a general fact that, in two dimensions, the Hodge dual of the one-form ι is a one-form dual to an axial-vector current (and conversely). The following considerations apply to any system in two space-time dimensions with a conserved vector current J^μ and an axial-vector current J_5^μ related to J^μ by Hodge duality. It follows from (12) that

⁸These formulae can be traced back to Tomonaga’s work on 1D electron liquids; see Tomonaga (1950) and Luttinger (1963).

⁹The author cannot guarantee that, in this section and in Sections “Anomalous current commutators and the chiral magnetic effect,” “A five-dimensional cousin of the Hall effect and axion electrodynamics,” and “3D Topological insulators and “axions,”” signs and factors of $1/2$, $1/2\pi$, ... are accurate everywhere.

¹⁰In classical physics, the role of $e\vec{E}$ is played by $M\vec{V} + \frac{M}{2}\vec{\nabla}|\vec{V}|^2$.

$$\partial_\mu J_5^\mu = \frac{Q}{\sqrt{2\pi}} \square \varphi. \quad (13)$$

Unitarity of the quantum theory of the field φ suggests that it satisfies a field equation of the form

$$\square \varphi = U'(\varphi, \partial_\mu \varphi, E),$$

where U' is the variational derivative with respect to φ of some functional U of φ , $\partial_\mu \varphi$ and the external electric field E (with U bounded below).

In the following, I consider systems in two space-time dimensions with the property that

$$U'(\varphi, \partial_\mu \varphi, E \equiv 0) = 0.$$

The field φ then describes noninteracting massless modes. It follows that J_5^μ is conserved as long as the external electric field vanishes. An example where this remark applies is a Tomonaga–Luttinger liquid (see Tomonaga, 1950; Luttinger, 1963) in the approximation where the dispersion law of the quasi-particles is linearized at the Fermi points. To summarize these remarks, we have that

$$\partial_\mu J_5^\mu = 0 \stackrel{(12), (13)}{\Leftrightarrow} \square \varphi = 0, \quad (14)$$

provided that $E = 0$; that is, φ is a *massless free field*, which can be described by a Lagrangian quantum field theory with an action functional given by

$$S(\varphi) = \frac{1}{4\pi} \int_\Lambda d^2x \sqrt{-g(x)} \partial_\mu \varphi(x) \partial^\mu \varphi(x), \quad \text{with } x \equiv (t, \underline{x}) \in \Lambda. \quad (15)$$

Assuming for simplicity that Λ is flat, the “momentum,” ϖ , canonically conjugate to φ is given by

$$\varpi(x) = \frac{\delta S(\varphi)}{\delta(\partial_0 \varphi(x))} = \frac{1}{2\pi} \frac{\partial \varphi(x)}{\partial t} = -\frac{1}{\sqrt{2Q}} J^1(x).$$

By Eq. (12),

$$J_5^0 = \sqrt{2Q} \varpi, \quad J_5^1 = \frac{Q}{\sqrt{2\pi}} \frac{\partial \varphi}{\partial \underline{x}}.$$

The usual equal-time canonical commutation relations on Fock space,

$$[\varphi(t, \underline{x}), \varpi(t, \underline{y})] = i \delta(\underline{x} - \underline{y}),$$

then imply an “anomalous current commutator”

$$[J^0(t, \underline{x}), J_5^0(t, \underline{y})] = i \frac{Q^2}{\pi} \delta'(\underline{x} - \underline{y}), \quad (16)$$

see (6), with $Q^2 = \alpha$. We define so-called chiral vertex operators, $\psi_{\ell/r}^{(q)}(x)$, by setting

$$\psi_{\ell/r}^{(q)}(x) =: \exp i \frac{q}{\sqrt{2}} \left[\pm \varphi(x) + 2\pi \int_{\underline{x}}^{\infty} \varpi(x^0, \underline{y}) d\underline{y} \right] :, \quad (17)$$

where the double colons indicate Wick ordering with respect to the free pseudo-scalar field with a *positive* mass (changing the mass used in the definition of Wick ordering just changes the fields $\psi_{\ell/r}^{(q)}(x)$ by a constant factor). When applied to a state in the Hilbert space of the system, the fields $\psi_{\ell/r}^{(q)}$ change the electric charge of the state by an amount $Q \cdot q$. The quantum statistics of the fields $\psi_{\ell/r}^{(q)}$ is determined by the phase factor $e^{\pm i\pi q^2}$ appearing in the Weyl relations of the vertex operator on the right side of (17). Thus, if $q = 1$ then $\psi_{\ell/r}^{(q)}$ is a *Fermi field*.

I hasten to add that the fields creating or annihilating *electrons* in an interacting Tomonaga–Luttinger liquid (Tomonaga, 1950; Luttinger, 1963) are in general not the ones given in (17); rather, they are composed of left-chiral and right-chiral vertex operators in a way determined by the strength of two-body interactions in the electron liquid (and by the requirements that they satisfy Fermi–Dirac statistics and create or annihilate an electric charge given by the elementary electric charge e).

To take into account the presence of an external electric field, E , the action functional $S(\varphi)$ in (15) must be replaced by

$$\begin{aligned} S(\varphi; A) &:= \frac{1}{4\pi} \int_\Lambda \partial_\mu \varphi \partial^\mu \varphi d^2x + \int_\Lambda A_\mu d^2x \\ &= \frac{1}{4\pi} \int_\Lambda \left\{ \partial_\mu \varphi \partial^\mu \varphi + 2\sqrt{2Q} \varepsilon^{\mu\nu} \partial_\nu \varphi A_\mu \right\} d^2x \\ &= \frac{1}{4\pi} \int_\Lambda \left\{ \partial_\mu \varphi \partial^\mu \varphi + 2\sqrt{2Q} \varphi E \right\} d^2x, \end{aligned} \quad (18)$$

where $E(x) = \varepsilon^{\mu\nu}(\partial_\mu A_\nu)(x)$. This formula can be derived from the theory of massless free Dirac fermions coupled to a vector potential A by convergent perturbation theory in the term $\int_\Lambda J^\mu A_\mu d^2x$ (see, e.g., Schwinger, 1962; Gattringer and Seiler, 1994). From expression (18) one easily derives the field equation for φ , which reads $\square \varphi(x) = \sqrt{2}Q E(x)$. Hence

$$\partial_\mu J_5^\mu = \frac{Q^2}{\pi} E(x), \quad (19)$$

which is the chiral anomaly in two space-time dimensions (interpreting Q^2 as the finestructure constant α).

Remarks on the chiral anomaly in four space-time dimensions will follow in Section “Anomalous current commutators and the chiral magnetic effect.”

A first application: Conduction quantization in quantum wires

The material presented in this section is taken from Alekseev et al. (1997, 1998). We consider a physical system consisting of a very long wire that contains a 1D interacting electron gas described by a Tomonaga–Luttinger liquid (setting $Q = -e$ in (11)) connected to electron reservoirs on the left end and the right end of the wire. We assume that there are no back-scattering processes converting left-moving quasi-particles (charge-density fluctuations) into right-moving ones, or conversely. Very close to the Fermi points of the electron gas, the electron dispersion law can be linearized, and quasi-particles can be described as massless relativistic chiral field modes. This system has a conserved vector current, $J^\mu = \frac{e}{\sqrt{2\pi}} \varepsilon^{\mu\nu} \partial_\nu \varphi$, and, in the “relativistic” approximation and for a vanishing external electric field, a conserved axial-vector current, J_5^μ , as discussed above. In the presence of a nonvanishing external electric field, E , with vector potential A_μ the currents

$$\hat{J}_{\ell/r}^\mu := J_{\ell/r}^\mu \mp \frac{Q}{2\pi} \varepsilon^{\mu\nu} A_\nu$$

are conserved, $(\partial_\mu \hat{J}_{\ell/r}^\mu = 0)$, but *not* gauge-invariant. However, the chiral charges

$$N_{\ell/r} := \int \hat{J}_{\ell/r}^0(t, \underline{x}) d\underline{x} \quad (20)$$

are *not only conserved*, but also *gauge-invariant*. It is important to observe (see Alekseev et al., 1998) that, if expressed in terms of the pseudo-scalar field φ introduced in (11) and (12), these charges are *independent* of the parameters describing the interactions in the Tomonaga–Luttinger liquid (Tomonaga, 1950; Luttinger, 1963).

Let H denote the Hamiltonian of the electron gas. The equilibrium state of this system at inverse temperature β is given by the density matrix

$$P_{\mu_\ell, \mu_r} := \Xi_{\beta, \mu_\ell, \mu_r}^{-1} \exp(-\beta H_{\mu_\ell, \mu_r}), \quad (21)$$

where $\Xi_{\beta, \mu_\ell, \mu_r}$ is the grand-canonical partition function, μ_ℓ and μ_r denote the chemical potentials of the electron reservoirs on the right end of the wire (injecting left-moving electrons into the wire) and on the left end of the wire, respectively, and

$$H_{\mu_\ell, \mu_r} := H - \mu_\ell N_\ell - \mu_r N_r.$$

Expectations with respect to P_{μ_ℓ, μ_r} are denoted by $\langle (\cdot) \rangle_{\mu_\ell, \mu_r}$. The electric current, I , flowing through the wire in the state $\langle (\cdot) \rangle_{\mu_\ell, \mu_r}$ is given by

$$I := \langle J^1(x) \rangle_{\mu_\ell, \mu_r} = -\frac{e}{\sqrt{2\pi}} \left\langle \frac{\partial \varphi(x)}{\partial t} \right\rangle_{\mu_\ell, \mu_r} = -i \frac{e}{\sqrt{2\pi}} \langle [H, \varphi(x)] \rangle_{\mu_\ell, \mu_r}, \quad (22)$$

where the last equation expresses the *Heisenberg equation of motion*. Formally, one has that

$$\langle [H, \varphi(x)] \rangle_{\mu_\ell, \mu_r} = \langle H \varphi(x) - \varphi(x) H \rangle_{\mu_\ell, \mu_r}. \quad (23)$$

Since the charges N_ℓ and N_r are conserved, one is tempted to conclude that the right side of this equation vanishes and, hence, that $I = 0$. This conclusion turns out to be *wrong* because the expression on the right of (23) is meaningless due to nontrivial zero modes of the field φ that can be present because φ is massless. In order to arrive at expressions that are meaningful, we replace the massless field φ used in the bosonization of the electron gas in the wire by a field with a small but *positive* mass that, at the end of our calculations, we will let approach 0. As long as this regularizing mass does not vanish, the Hamiltonian H does *not* commute with the charges N_ℓ and N_r , and hence (23) need *not* vanish. To find the correct expression for the current I passing through the wire, we use that

$$\begin{aligned} I &\stackrel{(23)}{=} -i \frac{e}{\sqrt{2\pi}} \langle [H, \varphi(x)] \rangle_{\mu_\ell, \mu_r} \\ &= -i \frac{e}{\sqrt{2\pi}} \langle [H_{\mu_\ell, \mu_r}, \varphi(x)] + [\mu_\ell N_\ell + \mu_r N_r, \varphi(x)] \rangle_{\mu_\ell, \mu_r} \end{aligned} \quad (24)$$

As long as the mass of φ is positive, we have that

$$\langle [H_{\mu_\ell, \mu_r}, \varphi(x)] \rangle_{\mu_\ell, \mu_r} = \langle H_{\mu_\ell, \mu_r} \varphi(x) - \varphi(x) H_{\mu_\ell, \mu_r} \rangle_{\mu_\ell, \mu_r},$$

and the right side of this identity is meaningful and *does* vanish, as follows from (21) and the cyclicity of the trace. Using Eq. (20) and the anomalous commutator (16), we find that the remaining terms on the right side of expression (24) for the current I add up to

$$\begin{aligned} I &= -\frac{ie^2}{2\pi}(\mu_\ell - \mu_r) \int \left\langle \left[\varpi(t, \underline{y}), \varphi(t, \underline{x}) \right] \right\rangle_{\mu_\ell, \mu_r} d\underline{y} \\ &= -\frac{e^2}{2\pi}(\mu_\ell - \mu_r), \end{aligned} \quad (25)$$

as follows from the canonical commutation relations between ϖ and φ . Eq. (25) remains true when the regularizing mass of φ tends to 0.

Notice that $-(\mu_\ell - \mu_r) =: \Delta V$ is the voltage drop through the wire. Re-installing Planck's constant $\hbar$, we find that

$$I = \sigma \Delta V, \quad \text{with} \quad \sigma = \frac{e^2}{2\pi\hbar}.$$

Since electrons have spin $\frac{1}{2}$, there are actually *two* species of charged particles (electrons with “spin-up” and “spin-down”) per nonempty band in the wire. Thus,

$$I = 2n \frac{e^2}{\hbar} \Delta V, \quad \text{for a wire with } n \text{ nonempty bands.}$$

This equation implies that the conductance σ in a quantum wire is quantized in even multiples of e^2/h .

For general results on transport in 1D systems exhibiting conformal symmetry, see Gawedzki and Tauber (2015), Gawedzki et al. (2018), and Moosavi (2021) and references given there.

What is fractional or braid statistics?

I have been encouraged to include in this review an outline of some basic facts about fractional or braid statistics.¹¹ This exotic form of quantum statistics makes its appearance in quantum (field) theories in $1+1$ and $2+1$ space-time dimensions. Quasi-particles with fractional statistics will appear in my discussion of the fractional quantum Hall effect in Section “The 2D quantum Hall effect.”

To start with, I propose to describe the exotic commutation relations between local quantum fields and certain fields localized on space-like rays, sometimes called *disorder fields*, in models of relativistic quantum field theory (rQFT) on two-dimensional (2D) Minkowski space, $\mathbb{M}^2$. This is the realm where *quantum fields* generalizing the well-known Bose and Fermi fields and giving rise to *fractional* or *braid statistics* were first discovered, at the beginning of the seventies of the past century (Klaiber, 1968; Streater and Wilde, 1970; Fröhlich, 1976, 1978); see also Fröhlich (1988b) (and Fredenhagen et al. (1989) for results inspired by Fröhlich (1988b)).

The Lorentz metric on $\mathbb{M}^2$ is given by

$$\left(\eta_{\mu\nu} \right) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

Two space-time points, $x = (x^0, x^1)$ and $y = (y^0, y^1)$, in 2D Minkowski space are *space-like separated* iff

$$(x - y)^2 := \sum_{\mu, \nu} (x^\mu - y^\mu) \eta_{\mu\nu} (x^\nu - y^\nu) < 0.$$

If two space-time points x and y are space-like separated then to say that “ x is to the left of y ”, namely $x^1 < y^1$, has an invariant meaning, that is, this statement is left unchanged by orthochronous Lorentz transformations of $\mathbb{M}^2$ of determinant 1.

The simplest rQFT on $\mathbb{M}^2$ is the theory of a free, massless scalar or pseudo-scalar field φ , which has been described in Section “The chiral anomaly,” Eqs. (15) and (17). We consider the fields $\psi_\ell^{(q)}(\cdot)$ introduced in Eq. (17). Recalling the Weyl form of Heisenberg's canonical commutation relations, one easily verifies that

$$\psi_\ell^{(q_1)}(x) \cdot \psi_\ell^{(q_2)}(y) = e^{i \pi (q_1 \cdot q_2)} \psi_\ell^{(q_2)}(y) \cdot \psi_\ell^{(q_1)}(x), \quad (26)$$

provided x is to the left of y ; if x is to the right of y then the sign in the exponent of the first factor on the right side of this equation changes. Note that if $q = 1$ then $\psi_{\ell/r}^{(q=1)}(\cdot)$ is a Fermi field (Klaiber, 1968; Streater and Wilde, 1970; Fröhlich, 1976, 1978). For future use we introduce the notation

¹¹The present section is somewhat abstract and sketchy; readers may want to skip it in a first reading.

$$R_{q_1, q_2}(\pm) := e^{\pm i \pi (q_1 \cdot q_2)}. \quad (27)$$

The commutation relations in (26) show that, for $0 < q < \sqrt{2}$ and $q \neq 1$, the field $\psi_\ell^{(q)}$ is neither a Bose field nor a Fermi field, but something in between. More generally, there are hybrids between left-chiral ($\psi_\ell^{(q)}$) and right-chiral ($\psi_r^{(q)}$) fields that satisfy commutation relations intermediate between those of Bose and Fermi fields typical of fractional statistics. Fields with commutation relations intermediate between Bose and Fermi commutation relations (see also Eq. 30) may appear in models of certain one-dimensional quantum chains exhibiting fractionally charged quasi-particles. Examples of such systems are discussed in Goldstone and Jackiw (1975), Heeger (1977), and Su and Schrieffer (1981).

Next, we consider an interacting rQFT in $1+1$ space-time dimensions, namely, a Lagrangian field theory of a two-component scalar field $\vec{\phi} = (\phi_1, \phi_2)$, whose action is given by

$$S(\vec{\phi}) = \int_{\mathbb{M}^2} dt d\mathbf{x} \left\{ \partial_\mu \vec{\phi}(x) \cdot \partial^\mu \vec{\phi}(x) - U(\vec{\phi}(x)) \right\}, \quad (28)$$

where U is a local self-interaction potential only depending on $\vec{\phi}$ which is invariant under the “clock transformations”

$$\begin{pmatrix} \phi_1 \\ \phi_2 \end{pmatrix} \rightarrow \begin{pmatrix} \cos \theta & \sin \theta \\ -\sin \theta & \cos \theta \end{pmatrix} \begin{pmatrix} \phi_1 \\ \phi_2 \end{pmatrix}, \quad \text{with } \theta = \{0, 2\pi/N, \dots, 2\pi(N-1)/N\},$$

representing the group $\mathbb{Z}_N = \mathbb{Z}/N\mathbb{Z}$. Let $[N]$ be the smallest even integer strictly larger than N . It is straightforward to check (exercise) that one can choose U to be a polynomial of degree $[N]$ in ϕ_1 and ϕ_2 that is $\mathbb{Z}_N$ -invariant and has deep minima along the rays

$$\{\lambda \vec{e}_n \mid \lambda > 0, \vec{e}_n := (\cos(2\pi n/N), \sin(2\pi n/N)), n = 0, 1, \dots, N-1\}.$$

Under suitable assumptions on the depth of minima of U in the directions $\vec{e}_n$ this theory has N disjoint vacuum states, $\langle \cdot \rangle_n$, $n = 0, 1, \dots, N-1$, with

$$\langle \vec{\phi}(0) \rangle_n = M \vec{e}_n \quad n = 0, 1, \dots, N-1, \text{ for some } M > 0.$$

There exist unitary disorder (soliton/kink) fields, $s_k(x)$, interpolating between these vacua, which are quasi-local with respect to $\mathbb{Z}_N$ -invariant Wick powers of $\vec{\phi}$ and are localized in a neighborhood of the point x , with the property that

$$\langle s_k(0, \underline{x}) \phi(0, \underline{y}) s_{-k}(0, \underline{x}) \rangle_n \rightarrow \begin{cases} M \cdot \vec{e}_n, & \text{as } \underline{y} \rightarrow -\infty, \\ M \cdot \vec{e}_{n+k}, & \text{as } \underline{x} \rightarrow +\infty. \end{cases} \quad (29)$$

Let $\varphi := \phi_1 + i\phi_2$; we introduce the fields

$$\Phi_k(x) := \varphi(x)^k : s_k(x), \quad k = 1, 2, \dots, N-1,$$

where the double colons indicate Wick ordering. We then find that if x and y are space-like separated

$$\Phi_k(x) \cdot \Phi_\ell(y) = e^{\frac{\text{sgn}(\underline{y}-\underline{x})}{2\pi N}} \Phi_\ell(y) \cdot \Phi_k(x), \quad \text{for } \underline{x} \ll \underline{y}, \quad (30)$$

the sign in the exponent of the first factor on the right side changing if $\underline{y} \ll \underline{x}$. Examples of such fields and their commutation relations were first considered in Fröhlich (1976); see also Fröhlich (1978). The ideas discussed in this paper (which triggered a little “industry”) are closely related to ideas concerning order and disorder fields in statistical mechanics proposed in Kadanoff and Ceva (1971) and Schroer (1982).

In Fröhlich (1988b), these commutation relations were generalized as follows: We consider “quasi-local order-disorder fields,” $\Phi_\alpha(x)$, $x \in \mathbb{M}^2$, $\alpha = 1, \dots, N$, for some $N < \infty$, and suppose that they satisfy commutation relations of the type

$$\Phi_\alpha(x) \cdot \Phi_\beta(y) = R_{\alpha\beta}^{\gamma\delta}(\sigma) \Phi_\gamma(y) \cdot \Phi_\delta(x), \quad (31)$$

provided x and y are space-like separated, with $(x-y)^2 \ll 0$, and $\sigma = \text{sign}(\underline{y}-\underline{x})$. It was shown in that reference that the associativity of the product of field operators implies that the $N^2 \times N^2$ -matrices $R(\sigma) = (R_{\alpha\beta}^{\gamma\delta}(\sigma))$ satisfy the Yang-Baxter equations, with $R(\sigma) \cdot R(-\sigma) = 1$. As the late Vaughan Jones¹² taught me in the spring of 1987, these R -matrices generate representations of the braid groups on an arbitrary number of strands.¹³ Consider n strands in $\mathbb{R}^3$ connecting points $(0, \underline{x}_1), \dots, (0, \underline{x}_n)$, with $\underline{x} = (x^1, x^2) \in \mathbb{R}^2$, to points $(t, \underline{x}_1), \dots, (t, \underline{x}_n)$, for some $t > 0$. The braid group, B_n , on n strands has generators τ_i , $i+1$ and $\tau_{i,i+1}^{-1}$, $i = 1, \dots, n-1$, which can be defined graphically (Fig. 1):

¹²See Jones (1983), Jones (1986), and Jones (1987) for his seminal work.

¹³In the nonabelian case, the commutation relations between quasi-local fields described by Eq. (31) require some understanding of quantum symmetries acting on the state spaces of nontrivial superselection sectors; this has been studied in much detail in Fröhlich and Kerler (1993).

Fig. 1 Generators of the braid groups on an arbitrary number n of strands.

A representation of B_n on the vector space $V_1 \otimes \cdots \otimes V_n$, $V_i \simeq \mathbb{C}^N, \forall i$, is obtained by

$$\tau_{i,i+1} \mapsto R(+)|_{V_i \otimes V_{i+1}}, \quad \tau_{i,i+1}^{-1} \mapsto R(-)|_{V_i \otimes V_{i+1}}, \quad i = 1, \dots, n-1,$$

with $R(\pm)$ as in Eq. (31).

Actually, these representations can also be derived from the monodromy of Euclidean Green functions of the fields Φ_z ; (see Tsuchiya and Kanie, 1987; Fröhlich, 1988a; Kohno, 1987). The R -matrices appearing in Eqs. (26) and (30) determine *abelian* representations of the braid groups. As discussed at some length in my paper Fröhlich (1988b) (and references given there), besides plenty of examples of massive rQFT models there are certain 2D conformal field theories, such as the Wess–Zumino–Witten models (Witten, 1984), with chiral primary fields giving rise to R -matrices in commutation relations of the form of (31) that determine *non-abelian* representations of the braid groups. If one studies the conformal blocks of these fields, one finds that they exhibit nontrivial monodromy determining representations of the pure braid groups and braid groups.

We define the “ n -point configuration space” M_n by

$$M_n := \{(z_1, \dots, z_n) \mid z_i \in \mathbb{C}, i = 1, \dots, n, z_i \neq z_j, \text{ for } i \neq j\},$$

where each $z_j := x_j + iy_j$, with $(x_j, y_j) \in \mathbb{R}^2, \forall j = 1, \dots, n$. The space M_n is not simply connected; its fundamental group is the pure braid group, P_n , on n strands. By $\tilde{M}_n$ we denote the universal cover of M_n . We define $M_n^{\text{sym}} := M_n/S_n$, where S_n is the symmetric group on n objects; the fundamental group of M_n^{sym} is the braid group, B_n , on n strands. In the presence of order–disorder fields, the Euclidean Green functions of quantum field models in $1+1$ dimensions,

$$G_n(z_1, \alpha_1, \dots, z_n, \alpha_n), \quad \alpha_j = 1, \dots, N, \text{ for } j = 1, \dots, n,$$

are multivalued distributions on M_n that give rise to single-valued distributions on $\tilde{M}_n$. In order to illustrate this fact, I consider the example of chiral primaries of the Wess–Zumino–Witten model with group $SU(M)$, $M \geq 2$, at level k . Let $X_\alpha, \alpha = 1, \dots, m \equiv M^2 - 1$, be a basis of the Lie algebra $\mathfrak{su}(M)$, and let $d\pi$ be a representation of $\mathfrak{su}(M)$ integrating to a representation π of $SU(M)$. The representation space of $d\pi$ is denoted by V . Let $V_1, \dots, V_n$ be n copies of V . We define

$$\Omega_{ij} := \sum_{\alpha=1}^m \mathbf{1}_{V_1} \otimes \cdots \otimes d\pi(X_\alpha)|_{V_i} \otimes \cdots \otimes d\pi(X_\alpha)|_{V_j} \otimes \cdots \otimes \mathbf{1}_{V_n}, \quad 1 \leq i < j \leq n. \quad (32)$$

These matrices satisfy the so-called infinitesimal pure braid relations (see Fröhlich (1988b) and references given there). Let $G(z_1, v_1, \dots, z_n, v_n), v_i \in V, \forall i = 1, \dots, n$, be the conformal blocks of chiral primaries of the WZW model at level k transforming under the representation π of $SU(M)$. These are holomorphic functions on $\tilde{M}_n$ satisfying the so-called Knizhnik–Zamolodchikov equations (Knizhnik and Zamolodchikov, 1984)

$$\frac{\partial}{\partial z_i} G(z_1, v_1, \dots, z_n, v_n) = \frac{2}{k+2} \sum_{j \neq i} \frac{1}{z_i - z_j} (\Omega_{ij} G)(z_1, v_1, \dots, z_n, v_n), \quad i = 1, \dots, n. \quad (33)$$

We note that the multivalued functions G are sections of a complex vector bundle with base space M_n and fiber $V^{\otimes n}$. The Knizhnik–Zamolodchikov equations (33) are nothing but the equations for parallel transport on this bundle determined by the flat connection ω given by

$$\omega = \frac{1}{k+2} \sum_{1 \leq i < j \leq n} \Omega_{ij} d \ln(z_i - z_j).$$

Flatness of ω is a consequence of the infinitesimal pure braid relations satisfied by the matrices $\Omega_{ij}, 1 \leq i < j \leq n$. The holonomies of this connection along noncontractible loops of M_n^{sym} determine a non-abelian representation of the braid group B_n for arbitrary $n = 2, 3, \dots$

Of course one may also interpret M_n^{sym} as the configuration space of n identical point particles moving in the plane $\mathbb{C}$ that are required to stay away from the diagonal $D_n := \{(z_1, \dots, z_n) \mid z_i = z_j, \text{ for some } i \neq j\}$. Let us suppose that the particles have an internal degree of freedom with values in a vector space V that is not “observable.” Quantum-mechanical wave functions of an n -particle system are then described by sections of a vector bundle with base space M_n^{sym} and fiber $V^{\otimes n}$ that is equipped with a flat connection $\omega = \sum_{1 \leq i < j \leq n} \Omega_{ij} d \ln(z_i - z_j)$, where the matrices $\Omega_{ij}, 1 \leq i < j \leq n$, satisfy the infinitesimal pure braid relations. The holonomies of ω along noncontractible loops in M_n determine a representation of the braid group B_n . Such wave functions come from single-valued functions on $\tilde{M}_n$. With inspiration provided by the Aharonov–Bohm effect, the simplest examples of the quantum

mechanics of such n -particle systems corresponding to nontrivial, but *abelian* representations of the braid groups B_n given by the matrices $R_{q_1, q_2}(\pm)$ in (26) (with $V = \mathbb{C}$) were discovered by Leinaas and Myrheim (1977). Their treatment was generalized by Goldin et al. (1980, 1981). In Wilczek (1982), Wilczek considered quantum field theories in $2 + 1$ dimensions describing particles, called “anyons,” with fractional spin and abelian braid statistics (see also Wu, 1984a, b). These matters are reviewed in Lundholm (2023), and I don’t have anything of great importance to add here. However, I propose to sketch how the braid statistics of superselection sectors, and of corresponding quasi-particles, appears in three-dimensional (3D) gauge theory. The results of Leinaas and Myrheim and of Wilczek can be viewed as special cases of such gauge theories.

I consider a 3D gauge theory with gauge group $G \stackrel{\text{e.g.}}{=} SU(M)$ on space-time $\mathbb{M}^3$. Let A denote the gauge potential of the theory, which is a 1-form on $\mathbb{M}^3$ with values in the Lie algebra, $\mathfrak{g}$, of the Lie group G , and let F_A denote the corresponding field strength, which is a 2-form on $\mathbb{M}^3$ with values in $\mathfrak{g}$. There may also be matter fields, $\Phi, \bar{\Phi}$, such as Higgs scalars, spinor fields, or nonrelativistic matter fields, transforming under certain finite-dimensional representations of G . The action functional, S , of the theory is given by

$$S(\Phi, \bar{\Phi}; A) := S_{\text{matter}}(\Phi, \bar{\Phi}; A) + g^{-2} \int_{\mathbb{M}^3} \text{tr} [F_A \wedge \tilde{F}_A] + CS(A), \quad (34)$$

where $\tilde{F}_A$ is the dual field strength, and

$$CS(A) := \frac{k}{4\pi} \int_{\mathbb{M}^3} \text{tr} \left[A \wedge dA + \frac{2}{3} A \wedge A \wedge A \right], \quad k \neq 0, \quad (35)$$

is the 3D Chern–Simons action. For $G = U(1)$, the constant k on the right side of (35) is an arbitrary real number, $dA = F_A$ is the electromagnetic field tensor, and the term $A \wedge A \wedge A$ vanishes. However, for $G = SU(M)$, the “level” k must be an integer; otherwise the integrand in the functional integral defining the theory would not be invariant under “large” gauge transformations. The example of a 3D abelian Higgs model ($G = U(1)$) has been treated in much detail in Fröhlich and Marchetti (1988), following the work in Wilczek (1982) and Wu (1984a, b). Among its “particles” this model describes magnetic vortices with fractional electric charge, fractional spin (given by a character, $s \in \mathbb{R}$, of the universal cover, $\widetilde{SO}(2) = \mathbb{R}$, of the group of space rotations in $\mathbb{M}^3$) and fractional statistics. The Euclidean Green functions of this model are described quite explicitly in Fröhlich and Marchetti (1988). Their monodromies determine abelian representations of the braid groups.

The results of Leinaas and Myrheim (see Leinaas and Myrheim, 1977) can be understood as arising from an abelian gauge theory with $G = U(1)$, where S_{matter} is the action of a system of an arbitrary number of conserved nonrelativistic particles coupled to a vector potential A , $g^{-2} = 0$ and k is an arbitrary real number. (The fields $\bar{\Phi}$ and Φ correspond to creation- and annihilation operators.)

An interesting special case of a 3D non-abelian gauge theory arises when we set

$$g^{-2} = 0, \quad S_{\text{matter}} = 0,$$

that is, *pure Chern–Simons theory*. This theory plays an important role in the theory of knots and links, as was recognized in Witten (1989) and Fröhlich and King (1989).

Pure Chern–Simons theory can be viewed as a Hamiltonian field theory, but with a vanishing Hamiltonian, exhibiting *static quasi-particles* that transform under finite-dimensional representations of the gauge group and satisfy non-abelian braid statistics. In a pure Chern–Simons theory with gauge group $SU(M)$ at level k , the wave functions of quasi-particles transforming under a representation π of $SU(M)$ on a finite-dimensional vector space V are given by the conformal blocks, $G(z_1, v_1, \dots, z_n, v_n)$, $v_i \in V, \forall i$, of an $SU(M)$ -WZW model at level k , which are solutions of the Knizhnik–Zamolodchikov equations displayed in Eq. (33). We choose coordinates $t := x^0$, $x_{\perp} := (x^+, x^-)$, on $\mathbb{M}^3$, with $x^+ = x^1 + ix^2$, $x^- = x^1 - ix^2$. In the Chern–Simons functional integral the conformal blocks $G(z_1, v_1, \dots, z_n, v_n)$ appear as expectations of *networks of (open) Wilson lines* carrying the representation π of $SU(M)$ with end points, $(t, z_1 = x_1^+), \dots, (t, z_n = x_n^+)$, in a plane at some fixed “time” t , provided one chooses the “light-cone gauge” to define the functional integral. The light-cone gauge is defined by

$$A = A_0 dt + A_+ dx^+ + A_- dx^-, \quad \text{with } A_- \equiv 0.$$

In this gauge, the action of Chern–Simons theory is quadratic in A , which enables one to “solve” the theory explicitly in terms of solutions of the Knizhnik–Zamolodchikov equations. This theme is developed in much detail in Fröhlich and King (1989), where, moreover, applications to pure mathematics (theory of knots and links) have been presented.

If one now assumes that the gauge coupling constant g in (34) is positive and finite and adds matter fields one is confronted with dynamical gauge theories with a positive mass gap and superselection sectors (and quasi-particles) satisfying fractional (braid) statistics. Such theories with gauge group $G = U(1)$ have been considered, for example, in Deser et al. (1982, 1988, 2000), Redlich (1984), and the fractionally charged magnetic vortices of these theories have been shown to satisfy abelian braid statistics in Wilczek (1982) and Fröhlich and Marchetti (1988). Dynamical gauge theories with non-abelian gauge groups, $G = SU(M)$, $M = 2, 3, \dots$, have been studied, for example, in Pisarski and Rao (1985).

A general, mathematically rigorous analysis of braid statistics and of the connection between spin and (braid) statistics in 3D local quantum theory has been presented in Fröhlich and Gabbiani (1990). Among the main conclusions of this paper are the following ones: The charged fields of a local quantum theory in $2 + 1$ space-time dimensions exhibit nontrivial fractional (braid) statistics *only* if (1) they are not localizable in bounded space-time regions (in fact, they are localized on space-like cones extending to infinity), which means, at least heuristically, that the theory is a *gauge theory*, (2) the charged states obtained by applying such fields to the vacuum state have fractional spin $s \notin \frac{1}{2}\mathbb{Z}$, and (3) the theory explicitly breaks the discrete symmetries of reflections in lines and time reversal (which, for a gauge theory, implies that its action contains a nontrivial Chern–Simons term). Well, there is

one class of physical systems that can be studied in the laboratory which satisfy all these requirements: 2D electron gases in an external magnetic field exhibiting the fractional quantum Hall effect. They are studied in the next section (see, in particular, the end of Section “Classification of “abelian” Hall fluids”).

The 2D quantum Hall effect

In this section we outline some important elements of the *theory of the quantum Hall effect* (QHE) (see Prange and Girvin, 1990; Chakraborty and Pietiläinen, 1988, and references given there). We consider the idealized set-up, sketched in Fig. 2, for measurements of the Hall conductivity (= Hall conductance) and the longitudinal resistance (or conductance) of a two-dimensional electron gas formed at the interface of a semiconductor and an insulator when a gate voltage perpendicular to the interface is turned on. The two-dimensional electron gas is assumed to be confined to a compact region, Ω , contained in the xy -plane and is subjected to a magnetic field $\vec{B}_0 \perp \Omega$ (parallel to the z -axis). To observe the quantization of the Hall conductivity, σ_H , the filling factor $\nu := n_e/(eB_0/h)$ of the electron gas (where n_e is the density of the gas, and $B_0 := |\vec{B}_0|$) must be chosen in such a way that the longitudinal resistance, R_L , of the electron gas vanishes (Fig. 2). (If the Hall (transverse) conductivity, σ_H , does not vanish, then

Fig. 2 Schematic representation of the experimental setup and of experimental results on the QHE. *Observations:* $R_L = 0 \leftrightarrow (\nu, \sigma_H) \in \text{plateau}$; plateau heights $\in \frac{e^2}{h} \mathbb{Q}$; the cleaner the sample, the more numerous are the observed plateaux and the narrower they are; if $\frac{h}{e^2} \sigma_H \notin \mathbb{Z}$, then there appear to exist quasi-particles with fractional electric charges.

$R_L = 0$ is equivalent to a vanishing longitudinal conductance.) To show, mathematically, that, for an *interacting* two-dimensional electron gas in a uniform external magnetic field, one can choose the filling factor ν in such a way that $R_L = 0$ appears to be a very hard problem of quantum many-body theory that has not been solved under realistic assumptions about the electron gas but has been extensively studied numerically (see, e.g., Morf, 1992). In the following, we attempt to solve a much easier problem: *Assuming* that $R_L = 0$, what can one say about the properties of the electron gas and, in particular, about the possible values of the Hall conductivity σ_H (under the condition that the diameter of Ω is much larger than the magnetic length)? This question has a very elegant, general answer (see Fröhlich and Studer, 1993; Fröhlich et al., 1996; Fröhlich, 1995; Fröhlich et al., 2001). In order to find this answer, we have to study the response of a 2D electron gas confined to Ω to a small perturbing electromagnetic field $(\vec{E}, \vec{B})$, with $\vec{E} \parallel \Omega$ and $\vec{B} \perp \Omega$. We set

$$\vec{B}^{tot} := \vec{B}_0 + \vec{B}, \quad B := |\vec{B}|, \quad \underline{E} := (E_1, E_2).$$

It is helpful to review the electrodynamics of 2D “incompressible” ($R_L = 0$) electron gases. The electromagnetic field tensor, $F = (F_{\mu\nu}) = (\partial_\mu A_\nu - \partial_\nu A_\mu)$, $\mu, \nu = 0, 1, 2$, in $2 + 1$ space-time dimensions is given by

$$F = \begin{pmatrix} 0 & E_1 & E_2 \\ -E_1 & 0 & -B \\ -E_2 & B & 0 \end{pmatrix}$$

The electric current density, j^μ , in the gas is given by

$$j^\mu(x) := \langle J^\mu(x) \rangle_A, \quad \mu = 0, 1, 2,$$

where $\langle (\cdot) \rangle_A$ denotes a (time-ordered) expectation in a very slowly varying external electromagnetic field with vector potential $A = (A_\mu)$.

The electrodynamics of 2D incompressible electron gases—Anomalous chiral edge currents

The basic equations of the $(2 + 1)$ -dimensional electrodynamics of 2D incompressible electron gases (in units where the speed of light $c = 1$) are as follows:

(i) **Hall's Law**—a phenomenological law

$$j^k(x) = \sigma_H \varepsilon^{k\ell} E_\ell(x), \quad k, \ell = 1, 2, \quad \text{assuming that } R_L = 0, \quad (36)$$

where $\varepsilon^{12} = -\varepsilon^{21} = 1$, $\varepsilon^{ii} = 0$, which shows that if $\sigma_H \neq 0$ the symmetries of reflections in lines (P) and time reversal (T) are broken. (Of course these symmetries are broken explicitly by the presence of an external magnetic field.)

(ii) **Charge conservation**—a fundamental law

$$\frac{\partial}{\partial t} \rho(x) + \nabla \cdot \underline{j}(x) = 0. \quad (37)$$

(iii) **Faraday's induction law**—a fundamental law

$$\frac{\partial}{\partial t} B_3^{tot}(x) + \nabla \wedge \underline{E}(x) = 0. \quad (38)$$

Combining Eqs. (i) through (iii), we obtain

$$\frac{\partial}{\partial t} \rho \stackrel{(ii)}{=} -\nabla \cdot \underline{j} \stackrel{(i)}{=} -\sigma_H \nabla \wedge \underline{E} \stackrel{(iii)}{=} \sigma_H \frac{\partial}{\partial t} B. \quad (39)$$

(iv) **Chern–Simons Gauss law**—(useful to determine the Hall conductivity)

Integrating (39) in time t , with integration constants chosen as follows

$$j^0(x) := \rho(x) + e \cdot n_e, \quad B(x) = B_3^{tot}(x) - B_0$$

we find the so called *Chern–Simons Gauss law* (see Eqs. (42) and (49))

$$j^0(x) = \sigma_H B(x). \quad (40)$$

As its derivation from (39) shows, this equation must be understood as saying that a small *change*, ΔB , of the external magnetic field transversal to the sample plane induces a small change, Δj^0 , in the charge density of the sample. Eq. (40) is also known under the name of *Streda formula*; see Streda (1982). Integrating both sides of Eq. (39) in time from $t = t_i$ to $t = t_f$ and over sample space Ω , we conclude that

$$\Delta Q = \sigma_H \Delta \Phi, \quad (41)$$

where ΔQ is the change of the electric charge stored in the sample and $\Delta \Phi$ is the change of the magnetic flux through the sample during the time interval $[t_i, t_f]$.

Remark. For 2D incompressible gases of *noninteracting* electrons moving in a disordered potential landscape, relation (41) has been invoked in calculations of the Hall conductivity, σ_H , with the purpose to exhibit its topological character (see Laughlin, 1981; Avron et al., 1990, 1994). But this law, as well as Hall's law (36) can equally well be used to calculate the Hall conductivity for incompressible *interacting* 2D electron gases and to exhibit the topological nature of σ_H . For example, one may consider an electron gas confined to a 2D torus, $\mathcal{T}$, and thread a magnetic flux tube through the interior of $\mathcal{T}$ that does not cross/intersect $\mathcal{T}$ and is parallel to a noncontractible cycle, γ , of $\mathcal{T}$.¹⁴ One may then ask how much electric charge, ΔQ_γ , crosses a cycle, $\tilde{\gamma}$, on $\mathcal{T}$ conjugate to γ (i.e., γ and $\tilde{\gamma}$ intersecting each other in a single point of $\mathcal{T}$) when the magnetic flux in the interior of the torus (parallel to γ) changes by an amount $\Delta \Phi$. A combination of Eq. (36) with Faraday's induction law (38) shows that the quotient $\Delta Q_\gamma / \Delta \Phi$ is given by σ_H . Assuming that the electric charge of all charge carriers in the system is an integer multiple of the elementary electric charge e , and assuming that the longitudinal conductance vanishes, one can invoke the theory of the Aharonov–Bohm effect to conclude that the state of this system is unchanged if the magnetic flux in the interior of $\mathcal{T}$ is slowly increased by an integer multiple of the flux quantum h/e . This implies that, in the process of increasing $\Delta \Phi$ by h/e , an integer number of charge carriers with a total electric charge Ne , $N \in \mathbb{Z}$, must cross the cycle $\tilde{\gamma}$. Hence

$$\Delta Q_\gamma = Ne = \sigma_H (h/e) \quad \Leftrightarrow \quad \sigma_H = N \frac{e^2}{h}, \quad N \in \mathbb{Z}.$$

These considerations do not explain why the “Hall fraction,” $\frac{h}{e^2} \sigma_H$, is often observed *not* to be an integer, but rather a *rational number* (most often with an odd denominator). It is plausible to imagine that if the Hall fraction is not an integer, then there must exist *fractionally charged quasi-particles*, as originally suggested by Tsui and Laughlin (see Section “Classification of ‘abelian’ Hall fluids”).

The sign of σ_H is determined by the nature of the quasi-particles carrying the Hall current, namely, whether these quasi-particles are electrons or holes. (Historically, this fact led to the discovery of holes in a nearly full conduction band of semiconductors.)

¹⁴Instead, we could consider a very large Corbino disk and study charge transport from the inner to the outer boundary circle when the magnetic flux threaded through its hole changes.

Hall's law (36) and the Chern–Simons Gauss law (40) yield the equation

$$j^\mu(x) = \sigma_H \varepsilon^{\mu\nu\lambda} F_{\nu\lambda}(x), \quad (42)$$

which is a *generally covariant* relation between the current density j^μ of the electron gas and the electromagnetic field tensor $F_{\nu\lambda}$.

Eq. (42) evokes to the following puzzle.

$$0 \stackrel{(ii)}{=} \partial_\mu j^\mu \stackrel{(iii), (42)}{=} \varepsilon^{\mu\nu\lambda} (\partial_\mu \sigma_H) F_{\nu\lambda}. \quad (43)$$

We observe that, while the left side of this equation vanishes by charge conservation, the right side does *not* vanish wherever the value of σ_H jumps, as, for example, at the boundary, $\partial\Omega$, of the sample region Ω . So, what is going on?

Solution of Puzzle: In Eq. (42), j^μ is the *bulk* current density, j_{bulk}^μ , which is apparently **not** conserved! The *conserved total electric current density*, j_{tot}^μ , can be decomposed into

$$j_{tot}^\mu = j_{bulk}^\mu + j_{edge}^\mu, \quad (44)$$

with

$$\partial_\mu j_{tot}^\mu = 0, \quad \text{but} \quad \partial_\mu j_{bulk}^\mu \stackrel{(43)}{\neq} 0.$$

We note that the support of the edge current density j_{edge}^μ coincides with the support of $\nabla\sigma_H$,

$$\text{supp } j_{edge}^\mu = \text{supp } \{\nabla\sigma_H\} \supseteq \partial\Omega, \quad \text{with} \quad j_{edge}^\mu \perp \nabla\sigma_H.$$

Combining (43) (setting $j^\mu = j_{bulk}^\mu$) with (44), we find that

$$\partial_\mu j_{edge}^\mu \stackrel{(44)}{=} -\partial_\mu j_{bulk}^\mu|_{\text{supp}\{\nabla\sigma_H\}} \stackrel{(42)}{=} -\varepsilon^{\mu\nu\lambda} \partial_\mu \sigma_H E_\nu.$$

When restricted to the support of $\nabla\sigma_H$, this equation becomes

$$\partial_\mu j_{edge}^\mu = -(\Delta\sigma_H) E_\parallel|_{\text{supp}\{\nabla\sigma_H\}}, \quad (45)$$

where $\Delta\sigma_H$ is the jump of the Hall conductivity across the edge in question. In the following, we assume that σ_H is constant throughout the interior of Ω and vanishes outside Ω (so that $\Delta\sigma_H = \sigma_H$ in (45)). This is not a realistic assumption; but it simplifies our discussion without introducing any misleading reasoning. Eq. (45) shows that j_{edge}^μ is an anomalous (chiral) current density in 1 + 1 dimensions. This equation can be viewed as a simple manifestation of “holography”: The edge displays as much information about the Hall conductivity of the system as the bulk.

Here is a classical physics argument determining the chirality of j_{edge}^μ : At the edge of the sample, the Lorentz force acting on electrons must be canceled by the force confining them to the interior of the sample. Thus,

$$\frac{e}{c} B^{tot} v_\parallel^k = e^{k\ell} \frac{\partial V_{edge}}{\partial x^\ell},$$

where V_{edge} is the potential of the force confining electrons to the interior of the sample region Ω . This enables us to find the equation for the chiral motion of degrees of freedom localized at the boundary, $\partial\Omega$, of the system (“skipping orbits”), and in particular for their propagation speed $v_\parallel$.

From the theory of the chiral anomaly in 1 + 1 dimensions, one may infer that, at the boundary $\partial\Omega$,

$$\partial_\mu j_{edge}^\mu = -\frac{e^2}{h} \left(\sum_{\text{species } \alpha} Q_\alpha^2 \right) E_\parallel \stackrel{\text{with (45)}}{\Rightarrow} \sigma_H = \frac{e^2}{h} \sum_{\text{species } \alpha} Q_\alpha^2 \quad (46)$$

where eQ_α is the “charge” (see 11) of the edge current, j_α^μ , corresponding to species α of clockwise-chiral edge modes; (similar contributions will come from counter-clockwise chiral edge modes, but with *reversed* sign).

Apparently, we have rediscovered *Halperin's* chiral edge currents (Halperin, 1982), but only using very general arguments that are valid even for interacting electron gases. We observe that if $\sigma_H \notin \frac{e^2}{h} \mathbb{Z}$, then there must exist chiral edge currents, j_α , with *fractional charge*, that is, with $Q_\alpha \notin \mathbb{Z}$, propagating along edges.

A phenomenon in classical physics analogous to the anomalous edge currents of 2D electron gases is found in the physics of hurricanes:

$$\vec{B} \rightarrow \vec{\omega}_{earth}, \quad \text{Lorentz force} \rightarrow \text{Coriolis force}, \quad V_{edge} \rightarrow \text{air pressure}.$$

This shows (among other things) that hurricanes on the northern hemisphere always turn anticlockwise. Related phenomena are the equatorial winds and chiral coastal water waves, called *Kelvin waves* (after Lord Kelvin, who discovered them). The take-home message of this observation is that anomalies, anomaly inflow and anomaly cancellation, are effects that already appear in classical

physics, in particular in the aerodynamics of the Earth's atmosphere and in the dynamics of fluids in noninertially moving containers, such as the Earth's oceans. (See Graf et al., 2021; Wiegmann and Abanov, 2022 for recent results on fluid dynamics.)

Next, we determine the (bulk and edge) effective action of 2D incompressible electron gases exhibiting the quantum Hall effect. As above, we consider a 2D electron gas in a neutralizing ionic background subject to a constant transversal magnetic field $\vec{B}_0$. The electrons are confined to a region Ω in the xy -plane. The space-time of the system is given by $\Lambda = \Omega \times \mathbb{R}$ (with $\mathbb{R}$ identified with the time axis). We suppose that the electrons are coupled to an external electromagnetic field with vector potential $A = A_0 dt + A_1 dx + A_2 dy$ describing a small, slowly varying perturbing electromagnetic field $(\underline{E}, B)$.

We assume that the 2D electron gas is an insulator, that is, that the longitudinal conductance vanishes. It is then easy to determine the form of the effective action, $S_{\text{eff}}(A)$, of this system as a functional of the external vector potential A in the limiting regime of very large distances and very low frequencies, that is, in the scaling limit; as alluded to in "Introduction: Gauge theory of states of matter" (see Fröhlich and Studer, 1993; Fröhlich et al., 1996 for details):

$$S_{\text{eff}}(A) = \frac{\sigma_H}{2} \int_{\Lambda} A \wedge [dA + K] + \text{boundary action} \\ + \frac{1}{2} \int_{\Lambda} d^3x \{ \underline{E}(x) \cdot \varepsilon \underline{E}(x) - \mu^{-1} B^2(x) \} + \dots, \quad (47)$$

where the first term on the right side is the topological Chern–Simons action (which is "marginal" in the infrared), and its coefficient, σ_H , turns out to be the *Hall conductivity*, K is the Gauss curvature 2-form on the sample space Ω , which gives rise to the famous "shift"; ε = tensor of dielectric constants, μ = magnetic permeability (and the first term on the second line of the right side of (47) is "irrelevant" in the infrared; the dots stand for further terms of even larger scaling dimension).

The presence of the Chern–Simons action on the right side of (47) can also be inferred from Eq. (42). Omitting curvature terms ($K = 0$),

$$j_{\text{bulk}}^{\mu} = \langle J^{\mu}(x) \rangle_A \equiv \frac{\delta S_{\Lambda}(A)}{\delta A_{\mu}(x)} \\ \stackrel{(42)}{=} \sigma_H \varepsilon^{\mu\nu\lambda} F_{\nu\lambda}(x), \quad \text{for } x \notin \partial\Lambda. \quad (48)$$

Integrating Eq. (48), we find that the effective action $S_{\text{eff}}(A) \equiv S_{\Lambda}(A)$ is given by

$$S_{\Lambda}(A) = \frac{\sigma_H}{2} \int_{\Lambda} A \wedge dA + \text{boundary action}. \quad (49)$$

That there *must* be a boundary action, denoted in the following by $\Gamma_{\text{edge}}(a)$, is a consequence of the fact that the Chern–Simons bulk action is *not* gauge-invariant on a space-time Λ with a nonempty boundary $\partial\Lambda$: Under a gauge transformation $A_{\mu} \rightarrow A_{\mu} + \partial_{\mu}\chi$, the Chern–Simons action changes by a boundary term

$$\frac{\sigma_H}{2} \int_{\partial\Lambda} [\chi dA]_{\partial\Lambda} \quad (50)$$

This anomaly must be canceled by the anomaly of a boundary action.

Returning to Eqs. (45) and (46), we guess that the boundary action must be the generating functional of the connected Green functions of the (quantum-mechanical) anomalous chiral edge current density

$$j_{\text{edge}}^{\mu} = \sum_{\alpha} j_{\alpha}^{\mu}, \quad \alpha = 1, 2, \dots,$$

where α labels the different species of charged chiral edge modes. The charge carried by j_{α}^{μ} has been denoted by eQ_{α} . Let v_{α} denote the propagation speed of the chiral modes that give rise to the edge current density j_{α}^{μ} . This propagation speed (which in general depends on the species α) plays the role of the "speed of light" in 2D current algebra. We introduce "light-cone coordinates," u^{+}, u^{-} , on $\partial\Lambda$. Let $a \equiv a_{+} du^{+} + a_{-} du^{-} := A_{\parallel}$ denote the electromagnetic vector potential (which is a 1-form) restricted to the 1 + 1-dimensional boundary, $\partial\Lambda$, of the (2 + 1)-dimensional space-time.

The effective action of the chiral edge current density j_{α}^{μ} is given by

$$\frac{(eQ_{\alpha})^2}{h} \Gamma_{\partial\Lambda}^{(\alpha)}(a), \quad \text{with } \Gamma_{\partial\Lambda}^{(\cdot)}(a) := \frac{1}{2} \int_{\partial\Lambda} \left[a_{+} a_{-} - a_{\pm} \frac{\partial_{\mp}^2}{\square} a_{\pm} \right] du^{+} du^{-}, \quad (51)$$

where $\square := \partial_{+} \partial_{-}$, and the choice of subscripts "+" and "-" in the last term on the right side of (51) depends on the chirality of the modes giving rise to the edge current j_{α}^{μ} (the dependence of $\Gamma_{\partial\Lambda}^{(\alpha)}(a)$ on α is determined by the chirality of the mode α and its propagation speed v_{α}).

The reader is invited to verify that the anomaly (50) of the bulk effective action, namely, the term $\frac{\sigma_H}{2} \int_{\partial\Lambda} [\chi dA]_{\partial\Lambda}$, is canceled by the anomaly of the edge effective action,

$$\Gamma_{edge}(a) := - \sum_{\text{species } \alpha} \frac{(eQ_\alpha)^2}{h} \Gamma_{\partial\Lambda}^{(\alpha)}(a), \quad (52)$$

under a gauge transformation $a \rightarrow a + d\chi|_{\partial\Lambda}$ if and only if

$$\partial_\mu (\delta \Gamma_{edge}(a) / \delta a_\mu(x)) = \partial_\mu j_{edge}^\mu(x) \equiv -\sigma_H^{edge} E_\parallel \stackrel{!}{=} -\sigma_H E_\parallel, \quad (53)$$

see (45); whence

$$\sigma_H^{edge} \stackrel{(52)}{=} \frac{e^2}{h} \sum_\alpha Q_\alpha^2 = \sigma_H. \quad (54)$$

This shows that edge and bulk Hall conductivities must *coincide*, as already emphasized in Fröhlich and Studer (1993) and Fröhlich et al. (1996). Merely for simplicity, we have assumed here (and will continue to assume in the following) that all edge modes have the *same* chirality; otherwise, appropriate signs have to be introduced in these formulae.

Whatever has been said here about Hall insulators also applies to so called *Chern insulators*, which break reflection- and time-reversal invariance *even* in the absence of an external magnetic field; for example, because the bulk of the material is doped by magnetic impurities (as in the Haldane model Haldane (1988); see also Fröhlich and Kerler (1991)).

Classification of “abelian” Hall fluids

In this section, I sketch a general classification of 2D insulators with broken parity and time reversal invariance (Hall or Chern insulators) exhibiting quasi-particles with *abelian braid statistics*.¹⁵ I will describe these systems in the limit of very large distance scales (i.e., I consider very large samples in units of the magnetic length) and of very low frequencies; that is, in the infrared *scaling limit*. Units will be used such that $\frac{e^2}{h} = 1$. Let J denote the total operator-valued electric current density (bulk plus edge current density), which is conserved: $\partial_\mu J^\mu = 0$.

Ansatz:

$$J = \sum_{\alpha=1}^N Q_\alpha J_\alpha, \quad (55)$$

where the currents J_α are assumed to be canonically normalized and conserved, with charges $Q_\alpha \in \mathbb{R}$.

Comment. This ansatz has been criticized, a common objection being that there is no reason why there should be more than *one* conserved current density, namely, the total electric current density. To counter this objection, I first consider a gas of electrons confined to a planar region Ω with the topology of a disk and a smooth boundary; a uniform external magnetic field transversal to Ω is turned on, and it is assumed that there are no electron–electron interactions. This system can be understood by studying the one-electron Hamiltonian: its eigenvalues form Landau levels. The eigenvalues corresponding to eigenfunctions localized close to the boundary, $\partial\Omega$, of Ω , are shifted upward to rather high energies by the boundary potential that confines the electrons to the interior of Ω (a fact that can be verified in perturbation theory); that is, the Landau levels end in bands of energies corresponding to chiral modes with eigenfunctions localized near $\partial\Omega$ and extended along $\partial\Omega$. The *ground state* of the electron gas is obtained by filling *all* the eigenstates corresponding to energy levels below the Fermi energy, E_F . Assuming that E_F is such that a certain number, N , of Landau levels are partially filled, then there are N energy bands corresponding to chiral boundary modes that are partially filled up to an energy $\leq E_F$. These bands and the Landau levels they emerge from correspond to separately conserved current densities.

If the electrons move in a disordered potential landscape, the energy eigenvalues of the Landau levels are spread out in “Landau bands.” Eigenvalues close to the edges of Landau bands correspond to localized eigenfunctions. But in the middle of each Landau band, there are eigenvalues corresponding to *extended* states. The eigenvalues corresponding to eigenfunctions localized near $\partial\Omega$ end in an energy band of chiral boundary modes that is close to the band found when the disorder potential vanishes (as follows from arguments similar to Halperin’s (Halperin, 1982)). By dilating the region Ω , one may approach the *scaling limit*. In this limit, the extended states in the middle of a filled Landau band (labeled by α) together with the corresponding states of chiral boundary modes with energies $\leq E_F$ then give rise to a current density, $J_\alpha^\mu := J_{bulk,\alpha}^\mu + j_\alpha^\mu$, which, at the very low frequencies that survive in the scaling limit, is *conserved*.

Thus, for noninteracting electron liquids, our ansatz appears to be justified in the scaling limit. (For finitely extended samples, there are corrections possibly describing some mixing of the currents, which, however, vanish in the scaling limit.)

For interacting electron liquids, the success of the **Ansatz** (55), which will be demonstrated below, appears to justify it. For an alternative ansatz, I refer to Fröhlich et al. (2001).

A topological field theory of conserved currents emerging in the scaling limit: On a 3D space-time $\Lambda = \Omega \times \mathbb{R}$, a conserved current J can be derived from a vector potential, B . If ι denotes the 2-form dual to J , then the continuity equation $\partial_\mu J^\mu = 0$ is equivalent to $d\iota = 0$. By Poincaré’s lemma,

¹⁵States exhibiting quasi-particles with *non-abelian braid statistics* are discussed in my work, Fröhlich et al., 2001, with B. Pedrini, Chr. Schweigert, and J. Walcher.

$$\iota = \frac{1}{\sqrt{2\pi}} dB,$$

where the vector potential B is a 1-form, which is determined by ι up to the gradient of a scalar function, β : B and $B + d\beta$ yield the same 2-form ι .

For a gapped 2D insulator, the effective field theory of the currents $(J_x)_{x=1}^N$ must be *topological* in the scaling limit. If the symmetries of reflection in lines and time reversal are broken, the “most relevant” term in the action functional of the potentials, $\underline{B} := (B_x)_{x=1}^N$, of the currents J_x is the *Chern–Simons action*

$$S_\Lambda(\underline{B}, A) := \sum_{x=1}^N \int_\Lambda \left\{ \frac{1}{2} B_x \wedge dB_x + A \wedge \frac{Q_x}{\sqrt{2\pi}} dB_x \right\} + \text{boundary terms} + \dots, \quad (56)$$

where A is the electromagnetic vector potential, and the boundary terms must be added to cancel the anomalies of the bulk action under the “gauge transformations”

$$B_x \rightarrow B_x + d\beta_x, \quad A \rightarrow A + d\chi.$$

Carrying out the oscillatory Gaussian integrals over the potentials B_x , we find

$$\begin{aligned} e^{iS_\Lambda(A)} &\equiv \mathcal{N}^{-1} \mathcal{Z}_\Lambda(A) := \mathcal{N}^{-1} \int \exp(iS_\Lambda(\underline{B}, A)) \prod_{x=1}^N \mathcal{D}B_x \\ &= \exp\left(i \frac{\sigma_H}{2} \int_\Lambda A \wedge dA + \Gamma_{\text{edge}}(A_\parallel)\right), \end{aligned} \quad (57)$$

where $\mathcal{N}$ is a normalization factor independent of A , and it follows from (56) that

$$\sigma_H = \frac{1}{2\pi} \sum_{x=1}^N Q_x^2,$$

(compare to formula (46)).

Physical states of the Chern–Simons theory with action as in (56) can be constructed from *Wilson networks*, W , of Wilson lines and Wilson flux tubes contained in the half space Λ_- , where $\Lambda_{+/-} := \Omega \times \mathbb{R}_{+/-} = \Omega \times \{t \mid t \geq 0/t \leq 0\}$, whose open lines/flux tubes end in $\Omega_0 \equiv \Omega \times \{t = 0\}$. Given such a network W , let $|W\rangle$ denote the physical state corresponding to W (see “[What is fractional or braid statistics?](#)”). Let $\Theta(W)$ denote the network contained in Λ_+ arising from W by reflection in Ω_0 , followed by complex conjugation. If W_1 and W_2 are two such networks with the property that their intersections with Ω_0 , more precisely their *fluxes* through Ω_0 , coincide we may consider the *gauge-invariant* network, $W_1 \circ \Theta(W_2)$, arising by multiplying W_1 with $\Theta(W_2)$; (graphically this amounts to concatenation at coinciding points/flux patches in Ω_0). Then the scalar product of the state $|W_1\rangle$ with the state $|W_2\rangle$ is given by

$$\langle W_2 \| W_1 \rangle := \mathcal{Z}_\Lambda(A)^{-1} \int (W_1 \circ \Theta(W_2))(\underline{B}) \exp(iS_\Lambda(\underline{B}, A)) \prod_{x=1}^N \mathcal{D}B_x. \quad (58)$$

Fact: The Hamiltonian of a Hall insulator described by (56) through (58) vanishes. Thus, in the scaling limit, all excitations are *static*.

The operator, $\mathcal{Q}_\mathcal{O}$, measuring the electric charge stored in states corresponding to Wilson networks whose supports intersect the sample space Ω_0 in a region $\mathcal{O}$ can be constructed from the Wilson loops

$$\exp(i\varepsilon \mathcal{Q}_\mathcal{O}) := \exp\left(i\varepsilon \int_\mathcal{O} \int_0^1 d^2x\right) = \exp\left(i \sum_{x=1}^N \varepsilon \frac{Q_x}{\sqrt{2\pi}} \int_{\partial\mathcal{O}} B_x\right), \quad \varepsilon \in \mathbb{R}.$$

Because the ground-state energy of a Hall insulator is separated from the rest of the energy spectrum by a strictly *positive (mobility) gap*, *electric charge* is a good quantum number to label its physical states at zero temperature. In other words, the charge operators

$$\mathcal{Q}_\mathcal{O} \quad \text{and} \quad \mathcal{Q} := \lim_{\mathcal{O} \nearrow \Omega} \mathcal{Q}_\mathcal{O}$$

are well defined on (zero-temperature) physical states.¹⁶

The electric charges, $q_{\mathcal{O},1}$ and $q_{\mathcal{O},2}$, contained in a region $\mathcal{O} \subset \Omega_0$ of two states $|W_1\rangle$, $|W_2\rangle$ with the property that $W_1 \circ \Theta(W_2)$ is gauge-invariant must be *identical*, that is, $q_{\mathcal{O},1} = q_{\mathcal{O},2} \equiv q_\mathcal{O}$. Their electric charge contained in $\mathcal{O}$, that is, the number $q_\mathcal{O}$, is given by

$$\exp(i\varepsilon q_\mathcal{O}) \langle W_2 \| W_1 \rangle = \mathcal{Z}_\Lambda(A)^{-1} \int (W_1 \circ \Theta(W_2))(\underline{B}) \exp(i\varepsilon \mathcal{Q}_\mathcal{O}) \exp(iS_\Lambda(\underline{B}, A)) \prod_{x=1}^N \mathcal{D}B_x, \quad (59)$$

¹⁶The same conclusion is reached by noticing that all Wilson loop expectations have perimeter decay and then invoking “t’Hooft duality.”

with $\varepsilon \in \mathbb{R}$ arbitrary. If a Wilson network W creates a physical state $|W\rangle$ describing n electrons or holes located inside a region $\mathcal{O} \subset \Omega_0$ when applied to the ground state of a Hall insulator, then the charge, $q_{\mathcal{O}} \equiv q_{\mathcal{O}}(W)$, contained in $\mathcal{O}$ is given by $q_{\mathcal{O}}(W) = -n + 2k$, where k is the number of holes in $\mathcal{O}$. If $-n + 2k$ is odd, that is, if n is *odd*, then the excitation created by W inside $\mathcal{O}$ must have Fermi–Dirac statistics, and if n is *even* it must have Bose–Einstein statistics; that is, there is a *connection between electric charge and quantum statistics* of electron-hole excitations.

Digression: Let W and W' be two Wilson networks both creating excitations describing $n - k$ electrons and k holes ($k = 0, 1, \dots, n$) located at *disjoint* points inside some region $\mathcal{O} \subset \Omega_0$, with $q_{\mathcal{O}}(W) = q_{\mathcal{O}}(W')$. Let $\widetilde{W}$ be an *arbitrary* Wilson network with the property that the networks $(W \cdot W') \circ \Theta(\widetilde{W})$ and $\mathcal{B}_{\mathcal{O}}(W \cdot W') \circ \Theta(\widetilde{W})$ are *gauge-invariant*, where $\mathcal{B}_{\mathcal{O}}(W \cdot W')$ arises from $W \cdot W'$ by braiding all lines of the two networks with endpoints inside $\mathcal{O}$, and *only* those, in such a way that the endpoints of all lines of W ending inside $\mathcal{O}$ are exchanged with the endpoints of all lines of W' ending in $\mathcal{O}$, but *without any lines twisted around or crossing each other*. Then (56) and (58) imply that

$$\langle \widetilde{W} \parallel \mathcal{B}_{\mathcal{O}}(W \cdot W') \rangle = \exp(i\pi n^2) \langle \widetilde{W} \parallel (W \cdot W') \rangle = (-1)^{q_{\mathcal{O}}} \langle \widetilde{W} \parallel (W \cdot W') \rangle.$$

This is the standard *connection between electric charge and statistics* of electron-hole excitations in a 2D incompressible electron gas. $\square$

Consider a Wilson network W with support in Λ_- that has just a single line, γ_p , ending in a point p contained in a region $\mathcal{O} \subset \Omega_0$, and let $q := (q^x)_{x=1}^N$ denote the quantum numbers (fluxes) dual to the potentials B_x attached to the line γ_p . Then W is given by the Wilson line

$$\exp\left(i \sum_{x=1}^N \sqrt{2\pi} q^x \int_{\gamma} B_x\right),$$

multiplied by lines or flux tubes contained in Λ_- that do *not* intersect Ω_0 in the region $\mathcal{O}$. It follows from Eq. (59) that

$$q_{\mathcal{O}}(W) = \sum_{x=1}^N Q_x q^x \equiv Q \cdot q, \quad (60)$$

where $Q = (Q_1, \dots, Q_N)$ and $q = (q^1, \dots, q^N)^T$. It is easy to argue that *quantum numbers, q , corresponding to multi-electron-hole excitations, form a module, Γ , over $\mathbb{Z}$ of rank N , that is, an integral lattice of rank N , which we call a “Hall lattice” (to see this, consider the additivity of the electric charge and other “pseudo-charge” quantum numbers q under multiplication of Wilson line insertions creating such excitations). By (60), the “vector” $Q = (Q_1, \dots, Q_N)$ must be an integer-valued, $\mathbb{Z}$ -linear functional on Γ , that is, an element of the dual lattice, Γ^* .*

The lattice Γ is equipped with an odd-integral quadratic form,

$$\langle q^{(1)}, q^{(2)} \rangle := \sum_x q^{(1)x} \cdot q^{(2)x}, \quad q^{(1)}, q^{(2)} \in \Gamma.$$

That this defines an odd-integral quadratic form is shown as follows: Braiding two Wilson lines with quantum numbers $q^{(1)} = q^{(2)} = q \in \Gamma$ ending in Ω_0 yields a phase factor $\exp(i\pi \langle q, q \rangle)$, which must be ± 1 if $Q \cdot q$ is even, and ± 1 if $Q \cdot q$ is odd (connection between electric charge and quantum statistics).

If q is the vector of quantum numbers corresponding to a single electron/hole, then

$$Q \cdot q = \mp 1, \text{ and } \exp(i\pi \langle q, q \rangle) = -1. \quad (61)$$

It follows that $\langle \cdot, \cdot \rangle$ is odd-integral, and that Q is a visible vector in Γ^* . Since $Q \in \Gamma^*$ and Γ is an (odd-) integral lattice, we conclude that (reinstating e^2/h)

$$\frac{h}{e^2} \sigma_H = Q \cdot Q \equiv \sum_{x=1}^N Q_x^2 \quad \text{is a rational number.} \quad (62)$$

Our task is then to classify the pairs (Γ, Q) of an odd-integral lattice Γ and a visible vector $Q \in \Gamma^*$ encoding physical properties of the corresponding incompressible 2D electron gases, using *invariants* of these data. This rather nontrivial task has been carried out in collaboration with U. M. Studer and E. Thiran, during the period from 1992 till 1994; see Fröhlich and Thiran (1994), Fröhlich et al. (1996), and Fröhlich (1995). I will not go into any details here. Among the results of our efforts we have predicted the table of Hall fractions in the interval $(0, 1]$ shown in Fig. 3; fractions indicated by a bullet (full dot) have been experimentally observed in incompressible electron gases exhibiting the quantum Hall effect. In Fig. 3, the Hall conductivity, $\sigma_H = \frac{e^2}{h} \cdot \frac{n_H}{d_H}$, is plotted horizontally (n_H and d_H are co-prime integers) and d_H is plotted vertically; units are chosen such that $e^2/h = 1$.

Fig. 3 Observed Hall fractions $\sigma_H = n_H/d_H$ in the interval $0 < \sigma_H < 1$, and their experimental status in single-layer 2D electron gases exhibiting the quantum Hall effect.

Comments. The Hall lattices Γ corresponding to fractions observed in the intervals $\Sigma_\ell^\pm, \ell = 2, 3, \dots$, (see Fig. 3) are related to those corresponding to fractions in the intervals $\Sigma_1^\pm$ by the so called *shift map*; see Fröhlich and Thiran (1994) and Fröhlich (1995). The pattern of Hall fractions in Σ_ℓ^- is much richer than the pattern in Σ_ℓ^+ : The Hall lattices Γ corresponding to the Hall fractions $\sigma_H = \frac{1}{3}, \frac{2}{5}, \frac{3}{7}, \dots$ contain the A - root lattices as their Witt sublattices¹⁷ and are *unique*. Among the Witt sublattices of the Hall lattices corresponding to Hall fractions in Σ_1^- one also finds the D - and the E - root lattices. For some of the fractions, such as $\sigma_H = \frac{2}{3}, \frac{3}{5}$, possibly $\frac{5}{7}, \dots$, one finds two or more *distinct* pairs (Γ, Q) of a quantum Hall lattice and a Q -vector associated with one and the same value of σ_H . The *experimental* manifestation of this ambiguity is that, at each of these values of σ_H , *transitions* between *distinct* Hall insulator states with the *same* value of the Hall conductivity are observed that are driven by changing the in-plane component of the external magnetic field (Eisenstein et al., 1990; Clark et al., 1990; Engel et al., 1992; Sajoto et al., 1990), which may affect the spin polarization of the electron gas, as predicted and explored in Morf and Halperin (1986) and Chakraborty (1986). For $\sigma_H \stackrel{\text{e.g.}}{=} \frac{1}{2}$ such transitions may be driven by changing the density of charge carriers in a wide quantum well, accompanied by a change in the external magnetic field, as studied in Suen et al. (1994).

The story just told can also be presented from the point of view of edge degrees of freedom. The chiral anomaly (46) and expression (54) imply that there must exist several (N) species of gapless chiral quasi-particles propagating along the edge. They are described by N chiral scalar Bose fields $\{\varphi^\alpha\}_{\alpha=1}^N$ with propagation speeds $\{v_\alpha\}_{\alpha=1}^N$, with the properties that

1. the chiral electric edge current operator and the Hall conductivity are given by the formulae

$$j_{edge}^\mu = e \sum_{\alpha=1}^N \frac{Q_\alpha}{\sqrt{2\pi}} \epsilon^{\mu\nu} \partial_\nu \varphi^\alpha, \quad \sigma_H^{edge} = \frac{e^2}{h} Q \cdot Q^T \stackrel{!}{=} \sigma_H, \quad \text{with } Q := (Q_1, \dots, Q_N);$$

and

¹⁷See, for example, Conway and Sloane (1993) for information about integral lattices and their invariants.

2. multielectron/hole states localized at an edge are created by the vertex operators

$$: \exp i \left(\sum_{\alpha=1}^N \sqrt{\pi} q_{\alpha} \varphi^{\alpha} \right) : , \quad \text{where} \quad q = \begin{pmatrix} q_1 \\ \vdots \\ q_N \end{pmatrix} \in \Gamma. \quad (63)$$

The connection between electric charge and (quantum) statistics valid in 1D "chiral Luttinger liquids" implies that Γ must be an odd-integral lattice of rank N (which is seen by arguments identical to the ones described above for the bulk of the electron liquid). If the Witt sublattice of a Hall lattice Γ contains the root lattice of a Lie algebra $\mathfrak{g}$, then $\mathfrak{g}$ must belong to the A , D or E series; and one finds that the chiral Luttinger liquid describing the edge degrees of freedom gives rise to a Kac–Moody algebra of chiral edge currents $\hat{\mathfrak{g}}_{k=1}$ at level 1.

A large family of Hall insulators can be classified by the data encoded into an odd-integral lattice Γ and a visible vector Q in the dual lattice Γ^* . As already mentioned, this implies that the Hall conductivity of such systems has the property that $\frac{h}{e^2} \sigma_H \in \mathbb{Q}$.

Remarks.

- I. It is expected that vectors q^* belonging to the dual lattice $\Gamma^* (\supset \Gamma)$ are the quantum numbers of quasi-particles with *fractional charge* and *fractional statistics*.
- II. Fractional electric charges of quasi-particles propagating along the edges/boundaries of a 2D incompressible electron gas can and have been measured by using Mach–Zehnder interferometry (see Glattli (2005); and Fröhlich et al. (2010), Bieri and Fröhlich (2012) for theory).
- III. The fractional quantum Hall effect might be observed in 2D-gapped electron gases with quasi-particles that obey *non-abelian braid statistics* (see Section "What is fractional or braid statistics?"; Moore and Read (1991), Fröhlich et al. (2001)). By dragging such quasi-particles adiabatically along nonintersecting world lines (braids) one could in principle realize quantum gates for quantum computation. This idea is described in Bonesteel et al. (2005).

Further details can be found in Fröhlich and Thiran (1994), Fröhlich et al. (1996), Fröhlich (1995), and Fröhlich et al. (2001).

Induced Chern–Simons actions, dualities, and 2D chiral photonic wave guides

We consider a model of 3D quantum electrodynamics (QED_3), namely, a relativistic quantum field theory of an odd number of Dirac fermions of electric charge e described by 2-component spinor fields, ψ_{α} , of masses $M_{\alpha} \neq 0$, $\alpha = 1, 2, \dots, 2n+1$, propagating in a three-dimensional space-time, $\Lambda (= \Omega \times \mathbb{R})$, and minimally coupled to an electromagnetic vector potential A . This theory breaks the symmetries of time reversal and reflection in lines. Integrating over the degrees of freedom of the Dirac fermions, we find that the effective action of the vector potential A is given by

$$\begin{aligned} S_{\Lambda}(A) &= \sum_{\alpha=1}^{2n+1} \ell n [\det_{ren} ((\partial_{\mu} - eA_{\mu}) \gamma^{\mu} + M_{\alpha})] \\ &= \sum_{\alpha=1}^{2n+1} \text{Tr} \ell n (1 - G_{M_{\alpha}} e A_{\mu} \gamma^{\mu}), \end{aligned} \quad (64)$$

where the matrices γ^{μ} , $\mu = 0, 1, 2$, are 2×2 Dirac matrices, and G_M is the propagator of a free 2-component Dirac spinor with mass $M \neq 0$ propagating in Λ ; (constants are ignored on the right side of (64)). One may expand the logarithm on the right side of (64) in powers of A . For a large value of the mass M , the leading term in $\text{Tr} \ell n (1 + G_M e A_{\mu} \gamma^{\mu})$ is the one quadratic in A , which can be calculated explicitly, as has been done by Deser et al. (1982, 1988, 2000) (see also Redlich (1984)).¹⁸ The quadratic term is given by

$$\text{sgn}(M) \frac{e^2}{8\pi\hbar} \int_{\Lambda} A \wedge dA + \text{boundary term}, \quad (65)$$

that is, by a Chern–Simons term corresponding to a Hall conductivity $\sigma_H = \pm \frac{1}{2} \cdot \frac{e^2}{h}$. Terms of higher order in A tend to 0, as $M \rightarrow \infty$. I will not reproduce the calculations leading to (65); but see Deser et al. (1982, 1988, 2000) and Redlich (1984).

If the electromagnetic field is treated as a dynamical quantum field, one must add a Maxwell term to the induced Chern–Simons action appearing on the right side of (64). Thus the total effective action functional of QED_3 is given by

$$\begin{aligned} S_{\Lambda}(A) &= \sum_{\alpha=1}^{2n+1} \text{sgn}(M_{\alpha}) \left\{ \frac{e^2}{8\pi\hbar} \int_{\Lambda} A \wedge dA + \Gamma_{\partial\Lambda}(A_{\parallel}) \right\} \\ &\quad + \int_{\Lambda} [\varepsilon \underline{E}^2 - \mu^{-1} B^2] d^3x + \text{less relevant terms}. \end{aligned} \quad (66)$$

Neglecting terms of higher than quadratic order in the electromagnetic vector potential A on the right side of (66), $S_{\Lambda}(A)$ is a quadratic form in the vector potential A . If Ω is a cube and periodic boundary conditions are imposed at $\partial\Omega$ (i.e., Ω is a torus), then

¹⁸This calculation also appeared in unpublished work on QED_3 by J. Magnen, the late R. Sénéor, and myself.

this quadratic form can be diagonalized by Fourier transformation. This yields an explicit (momentum-space) expression for the 2-point functions of the electromagnetic field tensor; general n -point functions can be expressed as sums of products of 2-point functions by appealing to Wick's theorem. The denominators of the imaginary-time (Euclidean) 2-point functions of the components, $F_{\mu\nu}$, of the electromagnetic field tensor in Euclidean energy-momentum space are given by $[k^2 + \text{const.}e^2]$, where k is the energy-momentum variable. This shows that, in this model of QED_3 , photons have a *strictly positive mass* proportional to e .

If space-time Λ has a boundary then the effective action of the electromagnetic field has a boundary term given by the anomalous chiral action $\sigma_H \Gamma_{\partial\Lambda}(A_{\parallel})$ cancelling the anomaly of the Chern-Simons term in (66), as discussed in (51) and (57).

It is argued that, in certain planar systems of condensed matter, there exist charged quasi-particles with low-energy properties mimicking those of 2-component Dirac fermions. An example is “doped” graphene (see, e.g., Semenoff, 1984; Giuliani et al., 2012, and references given there). The low-energy properties of such systems can be described by a theory approaching the model of QED_3 introduced above in the infrared domain.

In planar systems (i.e., systems in three space-time dimensions), the electromagnetic vector potential, A , and the vector potential, B , of the conserved electric current density, $J = \nabla \wedge B$, play *dual roles*: Under the replacements

$$A \mapsto B, \quad B \mapsto A, \quad (67)$$

one finds that the (leading terms in the) effective actions of *conventional time-reversal invariant 2D insulators* are mapped to the (leading terms in the) effective actions of *2D superconductors*, and *electronic Hall- or Chern insulators* are mapped to *gapped photonic wave guides* exhibiting extended chiral electromagnetic surface waves; and *conversely* (see Fröhlich et al., 1996).

As an example we consider the duality between certain Hall or Chern insulators and gapped photonic wave guides. We define an action functional depending on the vector potential B of a conserved vector current in an insulator breaking time-reversal invariance by

$$\tilde{S}_{\Lambda}(B) := \frac{1}{2\sigma_H} \int_{\Lambda} B \wedge dB + \text{boundary action} + \text{less relevant terms}, \quad \sigma_H := \frac{e^2}{4\pi\hbar}. \quad (68)$$

In the infrared domain, QED_3 with induced Chern-Simons action and the quantum theory of currents in Hall insulator are then seen to be related by duality, that is, by the replacements in (67). This is elucidated by functional Fourier transformation:

$$e^{i S_{\Lambda}(A)} = \mathcal{N}^{-1} \int e^{i \tilde{S}_{\Lambda}(B)} e^{i \int_{\Lambda} A \wedge dB} \mathcal{D}B, \quad (69)$$

where $\mathcal{N}$ is a normalization factor, and conversely. One may view the current driven through a planar wave guide with broken time-reversal invariance as a *classical control variable*, while the electromagnetic field is treated as a system of quantized *dynamical* degrees of freedom. The response equations of such a wave guide are then found to be given by

$$\langle F_{\mu\nu}(x) \rangle_B = \varepsilon_{\mu\nu\lambda} \frac{\delta \tilde{S}_{\Lambda}(B)}{\delta B_{\lambda}(x)} = \sigma_H^{-1} \varepsilon_{\mu\nu\lambda} j^{\lambda}(x). \quad (70)$$

The boundary action on the right side of Eq. (68) is given by $\frac{1}{\sigma_H} \Gamma_{\partial\Lambda}^{(\pm)}(B|_{\partial\Lambda})$, with

$$\Gamma_{\partial\Lambda}^{(\pm)}(b) := \frac{1}{2} \int_{\partial\Lambda} \left[b_+ b_- - 2b_{\pm} \frac{\partial_{\pm}^2}{\square} b_{\pm} \right] du^+ du^-$$

in light-cone coordinates (u^+, u^-) on $\partial\Lambda$, with $B|_{\partial\Lambda} = b_+ du^+ + b_- du^-$. The sign of σ_H and the choice of “ $\pm$ ” in $\Gamma_{\partial\Lambda}^{(\pm)}$ depend on the chirality of the electromagnetic edge waves. The boundary action $\Gamma_{\partial\Lambda}^{(\pm)}(b)$ is the generating functional of Green functions of *gapless edge modes of the quantized electromagnetic field* propagating chirally around the boundary of the wave guide. In the bulk of such wave guides, the electromagnetic field is gapped as remarked above.

It would be tempting to continue with a discussion of various further topics, such as the *theory of rotating Bose gases* in two dimensions and their Hall effects. This topic started with my work with U. M. Studer and E. Thiran (see Fröhlich et al., 1996). Much further work on 2D Bose gases has since been carried out in Cooper (2008) and Rougerie et al. (2014) (and references given there). The role of *gravitational anomalies* in an analysis of *heat transport* in 2D systems of condensed matter physics has been elucidated in Klevtsov and Wiegmann (2015) and Klevtsov et al. (2017).

Five-dimensional QED, a close cousin of the theory introduced in (64) through (66), will make a brief appearance in Section “A five-dimensional cousin of the Hall effect and axion electrodynamics” and might be of interest, for example, in cosmology.

Chiral spin currents in planar topological insulators

So far, we have ignored electron spin, in spite of the fact that there are 2D gapped electron gases exhibiting the fractional quantum Hall effect where electron spin plays an important role, as mentioned in Section “Classification of “abelian” Hall fluids.” (We won't study these systems any further; but see Fröhlich and Studer (1993), Fröhlich and Thiran (1994), and Fröhlich et al. (1996), and references given there.)

In this section we consider **2D time-reversal invariant topological insulators** exhibiting chiral spin currents.¹⁹ We start from the *Pauli equation* for the spinor wave function, Ψ_ν of a spinning electron

$$i\hbar D_0 \Psi_t = -\frac{\hbar^2}{2m} g^{-1/2} D_k \left(g^{1/2} g^{kl} D_l \Psi_t \right), \quad (71)$$

where m is the effective mass of an electron, (g^{kl}) is the inverse of the Riemannian metric on sample space, Ω , an orthonormal frame bundle is introduced on space-time $\Omega \times \mathbb{R}$ enabling one to define 2-component *Pauli spinors*, Ψ , and, in particular, to introduce notions of spin-up, $\uparrow$, and spin-down, $\downarrow$:

$$\Psi_t(x) = \begin{pmatrix} \psi_t^\uparrow(x) \\ \psi_t^\downarrow(x) \end{pmatrix} \in L^2(\Omega, d \text{ vol.}) \otimes \mathbb{C}^2.$$

Furthermore, the symbols D_μ , $\mu = 0, \dots, d$, $d = 2$ or 3 , are covariant derivatives

$$i\hbar D_0 = i\hbar \partial_t + e\varphi - \vec{W}_0 \cdot \vec{\sigma}, \quad \vec{W}_0 = \mu c^2 \vec{B} + \dots, \quad (72)$$

where φ is the electrostatic potential acting on the electrons, $\vec{W}_0 \cdot \vec{\sigma}$ is the Zeeman coupling of the spin of electrons to the zero-component, $\vec{W}_0$, of an $SU(2)$ -gauge field; $\vec{W}_0$ describes an external magnetic field and/or a Weiss exchange field (Albert et al., 2006). Furthermore,

$$\frac{\hbar}{i} D_k = \frac{\hbar}{i} \nabla_k + eA_k - \vec{W}_k \cdot \vec{\sigma} + \dots, \quad (73)$$

where $\vec{A}$ is the electromagnetic vector potential, and the dots stand for further terms present in a moving background (which we ignore in the following, but see Fröhlich et al., 1996); moreover, $\vec{W}_k$ is the k -component of an $SU(2)$ -gauge field, which, for the systems considered in this section, describes spin-orbit interactions, hence is given by

$$\vec{W}_k \cdot \vec{\sigma} := \left[(-\tilde{\mu} \vec{E} + \dots) \wedge \vec{\sigma} \right]_k, \quad (74)$$

where $\tilde{\mu} = \mu + \frac{e\hbar}{4mc^2}$: (the term $\frac{e\hbar}{4mc^2}$ is due to Thomas precession).

We observe that the Pauli equation (71) displays perfect $U(1)_{em} \times SU(2)_{spin}$ -gauge invariance. The $U(1)_{em}$ -connection, A , is given in terms of the electromagnetic potentials $\varphi =: A_0$ and $\vec{A}$ by $A = A_0 dt + A_1 dx^1 + \dots + A_d dx^d$, while $\vec{W} = \vec{W}_0 dt + \vec{W}_1 dx^1 + \dots + \vec{W}_d dx^d$ is the $SU(2)_{spin}$ -connection, with $x = (t \equiv x^0, x^1, \dots, x^d)$, $d = 2$ or 3 , the space-time coordinates on $\Lambda = \Omega \times \mathbb{R}$. (See Fröhlich and Studer (1993) and Fröhlich et al. (1996) for a more detailed discussion.)

In the following, we consider an interacting electron gas confined to a planar region Ω , setting $d = 2$ and $x^1 \equiv x$, $x^2 \equiv y$. We assume that $\vec{B} \perp \Omega$ and $\vec{E} \equiv \underline{E}$ is parallel to Ω . Then the $SU(2)_{spin}$ -connection, $\vec{W}_\mu$, is given by

$$W_\mu^3 \cdot \sigma_3, \quad \text{with } W_\mu^K \equiv 0, \text{ for } K = 1, 2, \quad (75)$$

with W_0^3 given by (72) and W_k^3 , $k = 1, 2$, given by (74). From (75), we conclude that, for the systems considered here, parallel transport of Pauli spinors splits into parallel transport for the spin-up ($\uparrow$) and the spin-down ($\downarrow$) components. The spin-up component, $\psi^\uparrow$, of a Pauli spinor Ψ couples to the *abelian* connection $a + w$, while $\psi^\downarrow$ couples to $a - w$, where

$$a_\mu = -eA_\mu, \quad \text{and } w_\mu = W_\mu^3, \quad (76)$$

see (72) and (74). Under time reversal, T ,

$$a_0 \rightarrow a_0, \quad a_k \rightarrow -a_k, \quad \text{but } w_0 \rightarrow -w_0, \quad w_k \rightarrow w_k. \quad (77)$$

The dominant term in the effective action of a 2D time-reversal invariant topological insulator, with $\vec{W}$ as in (75), is given by a combination of Chern-Simons terms. If either $w \equiv 0$ or $a \equiv 0$ a Chern-Simons term in a or in w alone would *not* be time-reversal invariant. Hence, assuming time-reversal invariance and $w \equiv 0$, the dominant term would be given by

$$S_\Lambda(A) = \int_\Lambda dt \, d^2x \{ e \underline{E}^2 - \mu^{-1} B^2 \}, \quad (78)$$

which is the effective action of a *conventional insulator*.

But, in the presence of both connections, a and w , a combination of *two* Chern-Simons actions is time-reversal invariant. The leading (“most relevant”) contribution to the (bulk) effective action is given by

$$\begin{aligned} S_\Lambda(a, w) &= \frac{\sigma}{2} \int_\Lambda \{ (a + w) \wedge d(a + w) - (a - w) \wedge d(a - w) \} \\ &= \sigma \int_\Lambda \{ a \wedge dw + w \wedge da \}, \end{aligned} \quad (79)$$

¹⁹ A general reference where the role of electron spin and spin currents and the spin Hall effect are analyzed is Dyakonov (2008).

where we have neglected the boundary (edge) actions.²⁰ The gauge fields a and w transform *independently* under gauge transformations preserving condition (75), and the action in (79) is *anomalous* under these gauge transformations, for a 2D sample space Ω with nonempty boundary. We have learned in Section “The 2D quantum Hall effect” that the anomalous boundary action,

$$\sigma \left[\Gamma_{\partial\Omega \times \mathbb{R}}^+ \left((a+w)_\parallel \right) - \Gamma_{\partial\Omega \times \mathbb{R}}^- \left((a-w)_\parallel \right) \right], \quad (80)$$

cancels the anomalies of the bulk action; see Eqs. (50) and (51). This boundary action is the generating functional of connected Green functions of *two counter-propagating anomalous chiral edge currents*. One of the two counter-propagating edge currents is carried by electrons with spin up ($\uparrow$), that is, spin polarization in the $+3$ -direction $\perp\Omega$, and the other one is carried by electrons with spin down ($\downarrow$). These edge currents are exchanged by time reversal. A net *chiral spin current*, s_{edge}^3 , can be excited to propagate along the edge of such a system. The bulk response equations (analogous to the Hall–Chern–Simons law (42)) are given by

$$j^k(x) = 2\sigma e^{k\ell} \partial_\ell B(x), \quad s_3^\mu(x) = \frac{\delta S_\Lambda(a, w)}{\delta w_\mu(x)} = 2\sigma e^{\mu\nu\lambda} F_{\nu\lambda}(x), \quad (81)$$

where we have expressed the $SU(2)$ -gauge field $\vec{W}$ in terms of the magnetic induction $\vec{B} = (0, 0, B)$ and the electric field $\vec{E} = (E_1, E_2, 0) = (E_1, E_2, 0)$. As in Section “The 2D quantum Hall effect,” Eqs. (43)–(45), (81) could again be used to deduce the existence of the edge spin currents discovered above.

We should ask what kinds of quasi-particles in the bulk of planar materials might produce the bulk Chern–Simons terms in (79). Given our findings in Section “Induced Chern–Simons actions, dualities, and 2D chiral photonic wave guides,” it is tempting to argue that a 2D time-reversal invariant topological insulator with a bulk effective action as given in (79) must exhibit two species of charged quasi-particles in the bulk, with one species (spin-up, $\uparrow$) related to the other one (spin-down, $\downarrow$) by time reversal, and each species has two degenerate states per wave vector mimicking a two-component Dirac fermion at small energies, leading to the quantization of σ .

Materials of this kind have been produced and studied in the laboratory of L. Molenkamp in Würzburg (see Franz and Molenkamp, 2013). The experimental data are not very clean, the likely reason being that, due to magnetic impurities in the material and/or electric fields in the direction $\perp\Omega$, the condition in (75) is violated, that is, the $SU(2)$ -gauge field $\vec{W}_\mu$ has nonvanishing components W_μ^K and is genuinely *non-abelian*. In this situation, the spin current is *not* conserved, anymore (but continues to be covariantly conserved, see Fröhlich and Studer, 1993), and time reversal invariance is broken.

The approach to 2D time-reversal invariant topological insulators sketched in this section can be generalized as follows: We consider a state of matter exhibiting a bulk spectrum of two species of quasi-particles related to one another by time reversal. In order to analyze the transport properties of such a state, one should study its response when one species is coupled to a (real or virtual, abelian or *non-abelian*) external gauge field W^+ and the other one to a gauge field W^- related to each other by time reversal according to

$$(W_0^+)^T = W_0^-, \quad (W_k^+)^T = -W_k^-.$$

If the leading term in the effective action for the gauge fields W^+ and W^- is given by the sum of two identical Chern–Simons terms, but with *opposite* signs, time-reversal invariance is manifestly preserved, and one concludes that there are *two counter-propagating chiral edge currents* generating current (Kac–Moody) algebras²¹ based on a Lie group given by the gauge group of the gauge fields $W^\pm$. For noninteracting electrons, this group can be determined from band theory.

If one gives up the requirement of time-reversal invariance, one arrives at a general theory of *chiral states* in 2D (planar) systems of condensed matter physics. If $\vec{W}$ is an $SU(2)$ -gauge field coupling to the spin of electrons, as in (72) and (74), one obtains a framework well suited to describe *chiral spin liquids* (see Fröhlich et al., 1996 and references given there).

Anomalous current commutators and the chiral magnetic effect

I recall the definition of left-handed and right-handed currents and the anomalous current commutators described in Section “The chiral anomaly” for theories in four space-time dimensions, namely

$$J_\ell^\mu := \frac{1}{2} [J^\mu + J_5^\mu], \quad J_r^\mu := \frac{1}{2} [J^\mu - J_5^\mu] \quad (82)$$

$$\left[J_{\ell/r}^0(\vec{y}, t), J^0(\vec{x}, t) \right] = \pm i \frac{\alpha}{8\pi^2} \left(\vec{B}(\vec{y}, t) \cdot \vec{\nabla}_{\vec{y}} \right) \delta(\vec{x} - \vec{y});$$

see Jackiw et al. (1986) and references given there, Faddeev (1984), and Fosco and Trincherio (1990) for a derivation using functional integrals.

I proceed to recall the *chiral magnetic effect* and its derivation from the anomalous commutator stated in (82). For this purpose I consider a theory of charged, massless Dirac fermions in four space-time dimensions. This theory has a conserved vector current, J^μ , satisfying the continuity equation

²⁰Note that if $\vec{W}$ is expressed in terms of $\vec{B}$ and $\vec{E}$ as in (72), (74), (75), one recovers expression (78). The effective action in (79) first appeared in a paper with U. M. Studer (Fröhlich and Studer, 1993) in 1993!

²¹At level 1, for noninteracting electrons.

$$\partial_\mu J^\mu = 0.$$

This equation implies that there exist two vector fields, $\vec{\varphi}(x)$ and $\vec{\chi}(x)$, such that

$$J^0(x) = \frac{e}{2\pi} \vec{\nabla} \cdot \vec{\varphi}(x), \quad \vec{J}(x) = -\frac{e}{2\pi} \left\{ \frac{\partial}{\partial t} \vec{\varphi}(x) + \vec{\nabla} \times \vec{\chi}(x) \right\}, \quad (83)$$

where e is the electric charge of the fermions. If H denotes the Hamiltonian of the system then the Heisenberg equations formally imply that

$$\frac{\partial}{\partial t} \vec{\varphi}(x) = \frac{i}{\hbar} [H, \vec{\varphi}(x)]. \quad (84)$$

We define chiral charges

$$N_{\ell/r} := \int d^3x \hat{J}_{\ell/r}^0(t, \vec{x}), \quad (85)$$

where

$$\hat{J}_{\ell/r}^\mu := J_{\ell/r}^\mu \mp \frac{e^2}{8\pi^2} \epsilon^{\mu\nu\rho\lambda} A_\nu F_{\rho\lambda}.$$

The second term on the right side of this equation is dual to the Chern–Simons 3-form, $A \wedge dA$, that we are already familiar with. Since the fermions are assumed to be massless, the charges $N_{\ell/r}$ are *conserved*, as follows from Eq. (7) in Section “The chiral anomaly,” and *gauge-invariant*.

Henceforth we suppose that all external fields, in particular the electromagnetic field, are *time-independent*. We may then consider an equilibrium state, $\langle (\cdot) \rangle_{\beta, \underline{\mu}}$ of the system with nonvanishing *chemical potentials*, $\underline{\mu} := (\mu_\ell, \mu_r)$, conjugate to the charges N_ℓ and N_r , respectively. Our aim is to calculate $\vec{j}(x) = \langle \vec{J}(x) \rangle_{\beta, \underline{\mu}}$, using arguments reminiscent of those in Section “A first application: Conduction quantization in quantum wires.” By Eqs. (83) and (84),

$$\vec{j}(x) = -\frac{ie}{\hbar} \langle [H, \vec{\varphi}(x)] \rangle_{\beta, \underline{\mu}} - \frac{e}{2\pi} \vec{\nabla} \times \langle \vec{\chi}(x) \rangle_{\beta, \underline{\mu}} \quad (86)$$

Formally, the term proportional to $\langle [H, \vec{\varphi}(x)] \rangle_{\beta, \underline{\mu}}$ vanishes because the equilibrium state is time-translation invariant. However, the field $\vec{\varphi}$ turns out to have ill-defined zero modes so that we cannot use the identity $[H, \vec{\varphi}(x)] = H\vec{\varphi}(x) - \vec{\varphi}(x)H$. We must regularize the right side of (86) by giving the field $\vec{\varphi}$ a small mass and then use that

$$\frac{\partial}{\partial t} \vec{\varphi}(x) = \frac{i}{\hbar} [H - \mu_\ell N_\ell - \mu_r N_r, \vec{\varphi}(x)] + \frac{i}{\hbar} [\mu_\ell N_\ell + \mu_r N_r, \vec{\varphi}(x)] \quad (87)$$

and that $\langle [H - \mu_\ell N_\ell - \mu_r N_r, \vec{\varphi}(x)] \rangle_{\beta, \underline{\mu}} = 0$. Combining this identity with (86) and (87), we find the *current sum rule*

$$\vec{j}(x) = -\frac{ie}{\hbar} \langle [\mu_\ell N_\ell + \mu_r N_r, \vec{\varphi}(x)] \rangle_{\beta, \underline{\mu}} - \frac{e}{2\pi} \vec{\nabla} \times \langle \vec{\chi}(x) \rangle_{\beta, \underline{\mu}}. \quad (88)$$

Recalling formula (82) for the anomalous current commutators and (83), we conclude that

$$\left[\hat{J}_{\ell/r}^0(\vec{y}, t), \vec{\varphi}(\vec{x}, t) \right] = \mp i \frac{e}{4\pi} \vec{B}(\vec{y}, t) \delta(\vec{x} - \vec{y}) + \vec{\nabla}_x \wedge \vec{\Pi}_{\ell/r}(\vec{x}, \vec{y}; t), \quad (89)$$

for some $\vec{\Pi}_{\ell/r}$. Using (85), (88), and (89), we find that the current density $\vec{j}$ is given by the equation

$$\vec{j}(x) = \frac{e^2}{4\pi\hbar} (\mu_\ell - \mu_r) \vec{B}(x) + \vec{\nabla} \times \vec{\mathfrak{B}}(x), \quad (90)$$

where the second term, proportional to $\vec{\mathfrak{B}}$, on the right side describes a persistent current not related to the magnetic induction $\vec{B}$, which we will not consider any further. Eq. (90) describes the *chiral magnetic effect* first considered in Vilenkin (1980) and Fukushima (2013) (see Alekseev et al. (1998) for a derivation along the lines of the arguments presented above). A more conceptual treatment of this effect is given in Section “A five-dimensional cousin of the Hall effect and axion electrodynamics.”

An effect related to the chiral magnetic effect might be observed in systems of spinning particles propagating in a *rotating (noninertially moving) background*, such as leptons in a rapidly rotating star.

A possible manifestation of the chiral magnetic effect in cosmology

In this section, we sketch ideas concerning the evolution of magnetic fields in an expanding Universe, that is, with a Hubble constant $\mathcal{H} \geq 0$, filled with a plasma of charged particles, assuming that there exists an asymmetry between right-handed and left-handed fermions so that the chiral chemical potential $\mu_5 := \mu_\ell - \mu_r$ does not vanish. In the following we use units such that the speed of light $c = 1$.

Faraday's induction law and the absence of magnetic monopoles are encoded in the homogeneous Maxwell equations

$$\vec{\nabla} \wedge \vec{E} = -\dot{\vec{B}}, \quad \vec{\nabla} \cdot \vec{B} = 0.$$

Coulomb's law and the Ampère-Maxwell law are encoded in the inhomogeneous Maxwell equations

$$\vec{\nabla} \cdot \vec{E} = j^0, \quad \vec{\nabla} \wedge \vec{B} = \dot{\vec{E}} + \mathcal{H}\vec{E} + \vec{j},$$

where $j = (j^0, \vec{j})$ is the vector current density of charged matter. We assume that the leading contribution to $\vec{j}$ is due to the *chiral magnetic effect*, besides a conventional contribution described by *Ohm's law*, that is,

$$\vec{j} = \frac{\alpha}{8\pi^2} \mu_5 \vec{B} + \sigma \vec{E}, \quad \alpha = \frac{e^2}{\hbar}, \quad (91)$$

where σ is the *Ohmic conductivity* of the plasma. Taking the *curl* of the Ampère-Maxwell law, with $\vec{j}$ as in (91), and using Faraday's induction law we find that

$$\square \vec{B} + \frac{\alpha}{8\pi^2} \mu_5 \vec{\nabla} \wedge \vec{B} + (\mathcal{H} + \sigma) \dot{\vec{B}} + \mathcal{O}(\mathcal{H}, \sigma \mathcal{H}, \mathcal{H}^2) = 0, \quad (92)$$

where $\square$ is the d'Alembert operator. The Hubble constant $\mathcal{H}$ is assumed to be slowly varying in time. From here on, the terms $\mathcal{O}(\mathcal{H}, \sigma \mathcal{H}, \mathcal{H}^2)$ in this equation are neglected. We solve Eq. (92) by Fourier transformation, using the ansatz

$$\vec{B}(\vec{x}, t) = \vec{b} e^{i(kz - \omega t)}, \quad \text{with } \vec{b} \perp z\text{-axis},$$

as required by the equation $\vec{\nabla} \cdot \vec{B} = 0$. Setting $\frac{\alpha}{8\pi^2} \mu_5 =: \tilde{\mu}$, the frequency $\omega(k)$ is found to be given by

$$\omega(k) = -i(\mathcal{H} + \sigma) \pm \sqrt{-(\mathcal{H} + \sigma)^2 + k^2 \pm \tilde{\mu}|k|}.$$

We observe that the assumptions that $\mathcal{H} \geq 0$ (expansion of the Universe) and $\sigma > 0$ (matter is a conducting plasma) lead to an *exponential damping* of $\vec{B}$ in time, *provided* that $|k| > \tilde{\mu}$. But if $|k| < \tilde{\mu}$ there exists a solution for which ω has a *positive* imaginary part, and the solution of (92) *grows exponentially*. This instability might be related to the growth of spatially very slowly varying primordial magnetic fields in the early Universe. Of course, the value of μ_5 is time-dependent, and it is expected that μ_5 tends to 0, as time t tends to ∞ . The instability described here will therefore come to an end, and the magnetic induction $\vec{B}$ will cease to grow.

A thorough analysis of this mechanism can be found in Fröhlich and Pedrini (2000), Boyarski et al. (2012), and Brandenburg et al. (2017), and references given there.

A five-dimensional cousin of the Hall effect and axion electrodynamics

We consider a system of charged matter at zero temperature coupled to an external electromagnetic field. In our derivation of the chiral magnetic effect (see (87)–(90)) we have assumed that the external electromagnetic field is *time-independent*. This is usually not the case, and in applications to cosmology and condensed matter physics, it is unrealistic to assume that $\mu_5 := \mu_\ell - \mu_r$ is independent of space and time. It turns out that a *dynamical analog* of μ_5 is known in particle physics under the name of “*axion*”. A very natural way of introducing axions is to study a cousin of the *quantum Hall effect* for a class of systems on a five-dimensional (space-time) slab, $\Lambda = \Omega \times [0, L]$, with two four-dimensional “boundary branes,” $\partial_\pm \Lambda \simeq \Omega$ parallel to the (x^0, x^1, x^2, x^3) -plane in five-dimensional Minkowski space, where x^0 is the time coordinate. The slab Λ is assumed to be filled with *very heavy four-component Dirac fermions* coupled to the 5D electromagnetic vector potential, $\hat{A}$ (viewed as a 1-form on Λ). Integration over the fermion degrees of freedom yields the effective action for $\hat{A}$, which has the form

$$S_\Lambda(\hat{A}) = \frac{1}{2L\alpha} \int_\Lambda d^5x \hat{F}_{MN}(x) \hat{F}^{MN}(x) + CS_\Lambda(\hat{A}) + \Gamma_\ell(\hat{A}|_{\partial_+ \Lambda}) + \Gamma_r(\hat{A}|_{\partial_- \Lambda}) + \dots, \quad (93)$$

where α is dimensionless, L is the width of the 5D slab Λ , and

$$CS_\Lambda(\hat{A}) := \frac{\kappa_H}{24\pi^2} \int_\Lambda \hat{A} \wedge \hat{F} \wedge \hat{F} \quad (94)$$

is the *5D Chern–Simons action*.²² For the time being, the vector potential $\hat{A}$ is treated as a classical external field. The action (94) predicts an analog of the Hall current given by

²²In this section we use units such that $\hbar = 1$.

$$j^M = \frac{\kappa_H}{8\pi^2} \varepsilon^{MNKL} F_{NJ} F_{KL}, \quad (95)$$

where the dimensionless constant κ_H plays the role of the Hall fraction $\frac{h}{e^2} \sigma_H$. The constant κ_H , related to the number of species of massive four-component Dirac fermions in the bulk, must be an integer for the functional integral to be well defined (assuming that all fermionic degrees of freedom have electric charges that are integer multiples of the elementary electric charge e). In the following I will set $\kappa_H = 1$. Eq. (95) should be compared to Eq. (42) of Section “The 2D quantum Hall effect.”

The action functional in Eqs. (93) and (94) describes the electrodynamics of a five-dimensional analog of the quantum Hall effect (5D QHE). Apparently, such 5D quantum Hall effects can be observed in certain systems of condensed-matter physics with virtual dimensions that play the role of space dimensions (see Price et al., 2015; Lohse et al., 2018 and references given there).

In (93), the functionals $\Gamma_{\ell/r}$ are the anomalous actions of left-handed/right-handed Dirac–Weyl fermions located on the boundary branes, $\partial_{\pm}\Lambda$. The action $\Gamma_{\ell} + \Gamma_r$ on the right side of (93) cancels the anomaly of the Chern–Simons action $CS_{\Lambda}(\hat{A})$; see Jackiw et al. (1986).

It is of interest to consider the *dimensional reduction* of the 5D theory with effective action given in (93) and (94) to a four-dimensional space-time, assuming that there is a gauge with the property that $\hat{A}_M$ is independent of x^4 , for all $M = 0, 1, 2, 3$. We define a field φ of scaling dimension 0, henceforth called *axion* field, by setting

$$\varphi(x) := \int_{\gamma_x} \hat{A}$$

where γ_x is a path parallel to the x^4 -axis connecting $\partial_{-}\Lambda$ to $\partial_{+}\Lambda$ at constant values of $x = (x^0, x^1, x^2, x^3)$. Then the action functional in (93) becomes

$$\begin{aligned} S_{\Omega}(A; \varphi) = & \frac{1}{2\alpha} \int_{\Omega} d^4x \left[F_{\mu\nu}(x) F^{\mu\nu}(x) + \frac{1}{L^2} \partial_{\mu} \varphi(x) \partial^{\mu} \varphi(x) \right] \\ & + \frac{1}{8\pi^2} \int_{\Omega} \varphi (F \wedge F) + \Gamma_{\Omega}(A) + \dots, \end{aligned} \quad (96)$$

Under the present assumptions on the vector potential $\hat{A}$, the term $\Gamma_{\Omega}(A) = \Gamma_{\ell}(A) + \Gamma_r(A)$ is *not* anomalous and is ignored in the following.

Expression (96) shows that the pseudo-scalar field φ can be interpreted as an *axion* field, whence its name. One can add a self-interaction term, $U(\varphi)$, to the Lagrangian density in (96), requiring that $U(\varphi)$ be periodic in φ with period 2π . From (96) we derive the equations of motion for $F_{\mu\nu} = \partial_{\mu} A_{\nu} - \partial_{\nu} A_{\mu}$ and φ .

$$\partial_{\mu} F^{\mu\nu} = -\frac{\alpha}{4\pi^2} \partial_{\mu} (\varphi \tilde{F}^{\mu\nu}), \quad L^{-2} \square \varphi = \frac{\alpha}{8\pi^2} F_{\mu\nu} \tilde{F}^{\mu\nu} - \frac{\delta U(\varphi)}{\delta \varphi}, \quad (97)$$

where $\tilde{F}^{\mu\nu}$ is the dual field tensor. These are the field equations of “axion-electrodynamics.” In terms of the electric and magnetic fields, these equations take the form

$$\begin{aligned} \vec{\nabla} \cdot \vec{B} &= 0, \quad \vec{\nabla} \wedge \vec{E} + \dot{\vec{B}} = 0, \\ \vec{\nabla} \cdot \vec{E} &= \frac{\alpha}{4\pi^2} (\vec{\nabla} \varphi) \cdot \vec{B}, \\ \vec{\nabla} \wedge \vec{B} &= \dot{\vec{E}} - \frac{\alpha}{4\pi^2} \{ \varphi \vec{B} + \vec{\nabla} \varphi \wedge \vec{E} \}, \end{aligned} \quad (98)$$

and

$$L^{-2} \square \varphi = \frac{\alpha}{4\pi^2} \vec{E} \cdot \vec{B} - \frac{\delta U(\varphi)}{\delta \varphi}. \quad (99)$$

A generalized chiral magnetic effect

If the axion field φ only depends on time then $\vec{\nabla} \varphi = 0$, and, comparing the right side of (98) with (90) and reinstating $\frac{e^2}{h}$, we find that

$$\dot{\varphi} = \mu_{\ell} - \mu_r \equiv \mu_5, \quad (100)$$

and (98) reproduces the equation describing the chiral magnetic effect; see Hehl and Obukhov (2003) and Fröhlich and Pedrini (2000).

In condensed matter theory, the equation of motion for $\dot{\varphi} \equiv \mu_5$ can take the form of a *diffusion equation*, including a term $\tau^{-1} \mu_5$, where τ is a relaxation time associated with the *dissipation* of the asymmetry between left- and right-handed degrees of freedom. Thus

$$\dot{\mu}_5 + \tau^{-1} \mu_5 - D \triangle \mu_5 = L^2 \frac{e^2}{2\pi h} \vec{E} \cdot \vec{B}, \quad (101)$$

where D is a *diffusion constant*, and it is assumed here that $U(\varphi) \equiv 0$. Eq. (101) implies that μ_5 approaches

$$\mu_5 \simeq \frac{\tau(L\epsilon)^2}{2\pi\hbar} \vec{E} \cdot \vec{B}, \quad (102)$$

as time t tends to ∞ (assuming that $\vec{E} \cdot \vec{B}$ is very slowly varying in space and time). This expression for μ_5 can be plugged into Eq. (90) for the current density $\vec{j}$, which then yields an expression for a conductivity tensor, $\sigma = (\sigma_{kl})$, in the presence of an external magnetic field given by

$$\sigma_{kl} = \frac{\tau(L\epsilon)^2}{4\pi^2} B_k B_l \quad (103)$$

This expression can be used in the study of transport properties of *Weyl semimetals*, to mention one example, which are considered in the next section.

Axion electrodynamics has intriguing applications not only in condensed-matter physics but also in the theory of heavy-ion collisions, in astrophysics, and in cosmology, where it may explain the growth of tiny, but highly uniform, cosmic magnetic fields extending over intergalactic distances, as mentioned in Section “A possible manifestation of the chiral magnetic effect in cosmology”; see Fröhlich and Pedrini (2000), Boyarski et al. (2012), Brandenburg et al. (2017), and Schober et al. (2018) and references given there.

For some purposes, it is of interest to assume that one boundary brane, for example, $\partial_- \Lambda$ (located at $x^4 = 0$), does not carry dynamical degrees of freedom, and that $\hat{A}|_{\partial_- \Lambda} = 0$ while $\hat{A}|_{\partial_+ \Lambda} =: A$ is arbitrary. We then set

$$\hat{A}_M(x, x^4) := \frac{x^4}{L} A(x)_\mu, \quad M \equiv \mu = 0, 1, 2, 3, \quad \hat{A}_4(x, x^4) =: \frac{1}{L} \varphi(x).$$

The axion field φ then transforms under an electromagnetic gauge transformations like an angle. From the action functional (93) of 5D Chern–Simons electrodynamics we derive the expression for the *gauge-invariant* action functional on four-dimensional space-time $\Omega (= \partial_+ \Lambda)$

$$\begin{aligned} S_\Omega(A, \varphi) := & \frac{1}{4\alpha} \int_\Omega d^4x \left[\frac{1}{3} F_{\mu\nu}(x) F^{\mu\nu}(x) \right. \\ & + L^{-2} (\partial_\mu \varphi(x) - A_\mu(x)) \cdot (\partial^\mu \varphi(x) - A^\mu(x)) \Big] \\ & + \frac{1}{8\pi^2} \int_\Omega \varphi(F \wedge F) + \Gamma_\ell(A) + \text{“irrelevant” terms.} \end{aligned} \quad (104)$$

This is the effective action of an anomaly-free 4D theory of chiral fermions coupled to electromagnetism and to an axion-like field φ that is *not* gauge-invariant.

3D Topological insulators and “axions”

In this last section, we study 3D topological insulators and Weyl semimetals on a sample space-time $\Lambda := \Omega \times \mathbb{R}$, with a nonempty boundary $\partial\Omega \times \mathbb{R}$. We are interested in the general form of the effective action describing the response of such systems to turning on an external electromagnetic field. Until the mid-nineties, the effective action of a 3D insulator was thought to be given by

$$S_\Lambda(A) = \frac{1}{2} \int_\Lambda dt d^3x \{ \vec{E} \cdot \epsilon \vec{E} - \vec{B} \cdot \mu^{-1} \vec{B} \} + \text{“irrelevant” terms}, \quad (105)$$

where ϵ is the tensor of dielectric constants and μ is the magnetic permeability tensor. The action defined in (105) is dimensionless. In the seventies, particle theorists taught us that one could add another dimensionless term, namely

$$S_\Lambda(A) \rightarrow S_\Lambda^{(\theta)}(A) := S_\Lambda(A) + \theta I_\Lambda(A), \quad (106)$$

where I_Λ is a “topological” term given by

$$\begin{aligned} I_\Lambda(A) &= \frac{1}{4\pi^2} \int_\Lambda dt d^3x \vec{E}(\vec{x}, t) \cdot \vec{B}(\vec{x}, t) \\ &= \frac{1}{8\pi^2} \int_\Lambda F \wedge F \stackrel{\text{Stokes}}{=} \frac{1}{8\pi^2} \int_{\partial\Lambda} A \wedge dA. \end{aligned} \quad (107)$$

In particle physics, the parameter θ is called “vacuum angle.” It is expected that the effective action of an insulator with broken parity and time reversal symmetries, after integration over all matter degrees of freedom, is given by the functional $S_\Lambda^{(\theta)}(A)$ introduced in (106) and (107). In the thermodynamic limit, $\Omega \nearrow \mathbb{R}^3$, $\exp[iS_\Lambda^{(\theta)}(A)]$ is periodic in θ with period 2π and invariant under time reversal iff $\theta = 0, \pi$. If $\theta = \pi$, on a space-time Λ with a nonempty boundary $\partial\Lambda$, the effective action $S_\Lambda^{(\theta)}(A)$ contains a contribution only depending on $a := A|_{\partial\Lambda}$ given by the Chern–Simons term

$$\Gamma_{\partial\Lambda}^{\text{CS}}(a) = \pm \frac{1}{8\pi} \int_{\partial\Lambda} a \wedge da, \quad (108)$$

which breaks time-reversal invariance. This term must be canceled by surface degrees of freedom²³ on $\partial\Lambda$ exhibiting a Hall conductivity of

$$\sigma_H = \mp \frac{1}{2} \cdot \frac{e^2}{h}. \quad (109)$$

We have encountered the action of Eq. (108) in Section “Induced Chern–Simons actions, dualities, and 2D chiral photonic wave guides” (see formulae (65), (66)). Up to further, “less relevant” and time-reversal invariant terms, it is the effective action of one species of 2-component Dirac fermions coupled to $a = A|_{\partial\Lambda}$. Gapless quasi-particles with spin $\frac{1}{2}$ propagating along $\partial\Lambda$ could mimic such Dirac fermions and cancel (108). The design of 3D materials with surface degrees of this kind is an interesting challenge.

The vacuum angle θ might be the ground-state expectation of a dynamical “axion” field, φ . The topological term $\theta I_\Lambda(A)$ would have to be replaced by

$$I_\Lambda(A, \varphi) := \frac{1}{8\pi^2} \int_\Lambda \varphi (F \wedge F) + S_0(\varphi), \quad (110)$$

where $S_0(\varphi)$ is invariant under shifts $\varphi \mapsto \varphi + 2n\pi$, $n \in \mathbb{Z}$. We then enter the realm of *axion electrodynamics*, as reviewed in Section “A five-dimensional cousin of the Hall effect and axion electrodynamics.”

Recalling the field equations (98), one rediscovers *Halperin’s 3D quantum Hall effect*: From Eq. (98) we infer a formula for the current density $\vec{j}$ in an external electromagnetic field and an “axion” field, namely

$$\vec{j} = -\frac{e^2}{2\pi h} \left(\vec{\varphi} \cdot \vec{B} + \vec{\nabla} \varphi \times \vec{E} \right) \quad (111)$$

I now consider a 3D *spatially periodic* system of matter with an emergent “axion,” φ . The underlying crystal lattice is denoted by $\mathcal{L}$. I suppose that φ is time-independent, that is, $\mu_5 = 0$. Taking into account the periodicity of $\exp(iI_\Lambda(A, \varphi))$ under shifts, $\varphi \mapsto \varphi + 2n\pi$, $n \in \mathbb{Z}$, invariance under lattice translations implies that

$$\varphi(\vec{x}) = 2\pi \left(\vec{K} \cdot \vec{x} \right) + \phi(\vec{x}), \quad (112)$$

where $\vec{K}$ belongs to the *dual lattice* $\mathcal{L}^*$, and ϕ is invariant under lattice translations. Neglecting ϕ , we find that $\vec{\nabla} \varphi = 2\pi \vec{K}$ is “quantized,” as $\vec{K}$ belongs to the *dual*, $\mathcal{L}^*$, of the crystal lattice $\mathcal{L}$. With (112) this implies that

$$\vec{j} = \frac{e^2}{h} \vec{K} \times \vec{E}, \quad \vec{K} \in \mathcal{L}^*.$$

This is Halperin’s 3D (*quantum*) *Hall effect* (Halperin, 1987; Kohmoto et al., 1992).²⁴

Next, I describe “axionic” effects in topological insulators with an effective action given by

$$S_\Lambda(A, \varphi) = S_\Lambda(A) + \frac{1}{8\pi^2} \int_\Lambda \varphi F \wedge F + S_0(\varphi), \quad (113)$$

see (110), where $S_0(\varphi)$ is now assumed to be invariant under shifts $\varphi \mapsto \varphi + n\pi$, $n \in \mathbb{Z}$. It is compatible with time-reversal invariance that $S_0(\varphi)$ has (well developed) minima at $\varphi = n\pi$. Then the material described by (113) is *not* an ordinary insulator. It may exhibit a *Mott transition*: At a positive temperature, the bulk of such a material contains *domain walls* across which the value of the axion field φ jumps by an integer multiple of π . Recalling the insight described after (108) and (109), we predict that such domain walls may carry gapless two-component Dirac-type fermions. At sufficiently high temperatures, some of these domain walls can be expected to become macroscopic, and this would then give rise to a *nonvanishing conductivity*; see Fröhlich and Werner (2013).

A curious effect somewhat related to the one described in Section “A possible manifestation of the chiral magnetic effect in cosmology” (see also Fröhlich and Pedrini, 2000) that could possibly be observed in materials with an effective axion has been pointed out in Ooguri and Oshikawa (2012): A time-independent external *electric field* $\vec{E}$ applied to an axionic magnetic material is *screened* once its strength exceeds a certain critical value, the excess energy being fed into the growth of a *magnetic field*.

Weyl semimetals

It may be argued that dynamical axions could emerge as effective degrees of freedom in

- certain 3D *topological insulators* with anti-ferromagnetic short-range order, (magnetic fluctuations playing the role of a dynamical axion)²⁵; and in
- crystalline 3D *Weyl semimetals*,

²³I am indebted to H.-G. Zirnstein for an instructive discussion of this point.

²⁴I am indebted to Greg Moore for a very instructive discussion of this effect.

²⁵A conjecture proposed by S.-C. Zhang and coworkers in Li et al. (2010), inspired by the work in Fröhlich and Pedrini (2000).

that is, in systems with two energy bands exhibiting two (or, more generally, an even number²⁶ of) double cones in quasi-momentum-frequency space corresponding to *chiral* quasi-particle states, assuming that the Fermi energy is close to the apices of those double cones; see Herring (1937) and Xu et al. (2015). At low frequencies, namely, near the apices of those double cones, the quasi-particle states of such systems are left- or right-handed Weyl fermions, respectively. In such systems, the time derivative, $\dot{\varphi} \equiv \mu_5$, of the “axion field” φ really has the meaning of a time-dependent *difference of chemical potentials* of left-handed and right-handed quasi-particles. It satisfies an equation of motion of the kind described in (101), that is,

$$\dot{\mu}_5 + \tau^{-1} \mu_5 - D \triangle \mu_5 = L^2 \frac{e^2}{2\pi h} \vec{E} \cdot \vec{B}. \quad (114)$$

A nonvanishing initial value of the chemical potential μ_5 may be triggered by strain applied to the system, leading to a left-right asymmetric population of the Fermi sea. Due to *inter-valley scattering processes*, a nonvanishing μ_5 will then relax toward 0, with a relaxation time corresponding to the parameter τ in Eq. (114). However, when applying a small external electric field $\vec{E}$ and a magnetic induction $\vec{B}$ to the system, with the property that $\vec{E} \cdot \vec{B} \neq 0$, one finds from (114) that μ_5 relaxes toward $\mu_5 \simeq \frac{\tau(Le)^2}{2\pi h} \vec{E} \cdot \vec{B}$. Thus, the conductivity tensor, $\sigma = (\sigma_{kl})_{k,l=1,2,3}$, is given by

$$\sigma_{kl} = \sigma_{kl}^{(0)} + \frac{\tau(L\alpha)^2}{4\pi^2} B_k B_l,$$

where the first term on the right side is the standard Ohmic conductivity (due to phonon and impurity scattering), and the second term is a manifestation of the *chiral magnetic effect*; see Eq. (103).

Conclusion

I conclude this contribution with some general remarks, including ones about what is missing in it and a few personal ones.

1. I hope that this review shows that the physics of systems of condensed matter in two and three dimensions, and in particular of (topological) insulators, is very rich. It has potential to find promising technological applications. Mathematical techniques ranging from abstract algebra over the topology of fiber bundles all the way to hard analysis have interesting and often surprising applications in the study of these fascinating states of matter. Electron gases, magnetic materials, Bose gases, etc. offer many challenges to experimentalists and theorists. General principles and interesting features of quantum theory, such as braid statistics, fractional spin and fractional electric charges (see Sections “What is fractional or braid statistics?” and “The 2D quantum Hall effect”), anomalies and their cancellation, current algebra, and holography enter the arena of condensed matter physics. Exotic species of quasi-particles, in particular, quasi-particles with braid statistics, two-component Dirac-like and Weyl fermions and Majorana fermions are encountered in the physics of various two- and three-dimensional systems of condensed matter explored, theoretically and experimentally, in recent years.
2. An important goal in this contribution has been to review some of the results in theoretical condensed matter physics that are *not* limited to non-interacting electron gases, but apply to correlated systems exhibiting interaction effects. I hope that I have reached this goal and that this review shows that concepts and methods from quantum field theory pioneered in particle physics can be used to one’s advantage to study general features of *interacting* systems in condensed matter physics. In particular, these methods are very useful to characterize and classify plenty of examples of *topological states of matter*, in particular ones that do not have any local order parameters so that conventional Landau theory is not applicable. The best explored examples are 2D incompressible electron gases in an external magnetic field exhibiting the fractional quantum Hall effect; see Prange and Girvin (1990), Chakraborty and Pietiläinen (1988), Fröhlich and Thiran (1994), and Fröhlich et al. (1996) and references given there. In this review the emphasis is on showing how concepts from *quantum gauge theory*, such as effective actions, power counting, gauge invariance, the chiral anomaly and some of its consequences, such as the chiral magnetic effect, θ -ground states, axion electrodynamics, quasi-particles with braid statistics, etc. can be used to come up with nontrivial and often quite surprising insights into properties of states of systems of condensed matter that have attracted much interest in recent years. The general formalism reviewed in this paper can thus rightly be called *Gauge Theory of States/Phases of Matter*. The rather ambitious goals of the efforts reviewed in this article may explain why mathematical rigor has not been the main concern—the mathematical complexity of quantum-mechanical many-body theory of interacting/correlated systems is well known to be awesome. I hope that, in spite of its somewhat abstract style and in spite of employing concepts first developed in particle physics, this review will contribute to making efforts in theoretical condensed matter physics by my collaborators and myself and many other somewhat mathematically oriented colleagues a little more widely known and appreciated.²⁷

²⁶This follows from the celebrated Nielsen–Ninomiya theorem; see Friedan (1982) and references given there.

²⁷To read, to mention but one example (see Landsteiner, 2022), that it is *only during the past decade* that the chiral anomaly has been used in the study of transport phenomena in condensed matter physics makes me wonder whether communication channels within the scientific community are congested (to put it politely). Of course, there are also plenty of examples of this congestion in the mathematical physics community.—In all modesty I claim some credit for my collaborators and myself for having developed a useful formalism, emphasizing connections to particle physics and quantum field theory including gauge theory and the chiral anomaly, for the study of “topological states of matter,” starting more than thirty years ago.

3. What is clearly and most regrettably missing in this review is an account of the *bare-hands analysis* of spectral properties of many-body Hamiltonians describing “topological states of matter” at energies quite close to the ground-state energy and to derive properties of quasi-particles and of transport, using a variety of powerful analytical tools, such as multiscale analysis²⁸ and renormalization group methods. Colleagues who have devoted very substantial efforts extending over many years toward reaching results in this direction are T. Balaban, F. Dyson, J. Feldman, G. Gallavotti, A. Giuliani, H. Knörrer, E. H. Lieb, J. Magnen, V. Mastropietro, W. Pedra, A. Pizzo, M. Porta, V. Rivasseau, M. Salmhofer, B. Schlein, R. Seiringer, E. Trubowitz, J. Yngvason, and others. References to early work by some of these colleagues can be found in my Les Houches lectures [Chen et al. \(1994\)](#) of 1994; among a variety of recent contributions toward understanding analytical aspects of the quantum Hall effect are the papers quoted in [Giuliani et al. \(2012, 2017\)](#) and [Mastropietro and Porta \(2022\)](#). Further references to many important results in mathematical quantum many-body theory, due to colleagues mentioned in this paper and numerous other researchers, can easily be found on “arXiv” and “google scholar.” I strongly recommend their papers to the attention of the reader. Obviously plenty of fascinating open problems remain to be tackled.

Acknowledgments

I am immensely grateful to my many collaborators who have joined me on our sometimes arduous journey through some provinces of condensed matter physics, including the following colleagues: C. Albert, A. Alekseev, S. Bieri, A. Boyarsky, V. Cheianov, T. Chen, L. Ferrari, R. Götschmann, G.-M. Graf, T. Kerler, A. Knowles, I. Levkivskyi, P.-A. Marchetti, B. Pedrini, A. Pizzo, O. Ruchayskiy, B. Schlein, Chr. Schweigert, T. Spencer, U. M. Studer, E. Sukhorukov, E. Thiran, J. Walcher, Ph. Werner, and A. Zee. I am very grateful to the late R. Morf for having introduced me to the miracles of the quantum Hall effect, for many discussions and for his criticism, to P. Wiegmann for very helpful discussions and encouragement, and to M. Zirnbauer for his kind interest, extending over many years, in my efforts and for having invited me to a workshop at the Schrödinger Institute in Vienna and for a series of lectures at Bad Honnef, on which this review is based. I am indebted to T. Chakraborty for giving me this opportunity to present my point of view on some topics in condensed matter physics and for suggesting some clarifications in this text. I have profited from what colleagues at ETH Zurich and elsewhere, too many to be listed here, have taught me in numerous discussions.

Abstract

An overview is given of the 2D many-anyon gas, including its definition (both for ideal and certain less-than-ideal particles and for abelian and non-abelian braid group representations), its corresponding known properties starting out from the intricate relationship between exchange and exclusion, as well as its emergence from bosons and/or fermions in 3D.

Key points

- How can the 2D anyon gas be defined physically and modeled mathematically?
- What are the essential properties of the anyon gas? Does it admit some notion of exclusion statistics intermediate to bosons and fermions?
- How can an anyon gas emerge in a realistic physical system consisting of only bosons and/or fermions?

Introduction

Quantum statistics refers to the symmetry and organizing principle assumed by the components of a quantum system. Primarily we think of particles, described by a joint state or wave function, which can fall into certain symmetry classes due to the fundamental constraints on the information that can be extracted from the system, such as those imposed by the uncertainty principle. **Bosons** and **fermions** are ensembles of identical such particle subsystems characterized by symmetry, respectively antisymmetry, with respect to particle exchange. In their ideal limits they manifest the statistical state distributions defined by Bose and Einstein, respectively Fermi and Dirac, with the latter subject to Pauli's exclusion principle. In a sense, whereas bosons unify, fermions individualize. **Anyons** are defined as identical quantum particles with an intermediate exchange symmetry characterized by representations of the braid group, which is the relevant group of continuous exchanges of particle configurations in 2D (two spatial dimensions). An **anyon gas** is a quantum system consisting of a large number of such particles subject to a fixed class of exchange symmetries, which is dependent on the specific underlying kinematics and dynamics of the quantum systems from which it emerged. The study of the behavior of the proper anyon gas presents a significant challenge to mathematics and physics. Our aim with this overview is to make these statements precise and to give an updated status report on some of the many facets of the topic.

Brief historic overview

For completeness and to set our reference point for this overview, we give a very brief account on the origins of the anyon gas, referring to Biedenharn et al. (1990), Fröhlich (1990), Leinaas and Myrheim (2022), and Goldin (2022) for further background.

Three perspectives on anyons

The discovery of anyons and intermediate quantum statistics in two spatial dimensions may be attributed to three independent research groups, working from three distinctly different perspectives (These three groups were initially unaware of each other's earlier contributions, and their initial works therefore lack the respective citations. There have subsequently been attempts to remedy this in the literature (Biedenharn et al., 1990).). Chronologically, these are (cf. Fig. 1):

1. **Geometric:** In 1977, Leinaas and Myrheim used geometric methods from gauge theory, fiber bundles, and extensions of the kinetic energy operator via boundary conditions (also known as “Schrödinger quantization”) to arrive at the possibility for what they termed “intermediate statistics” in 2D (as well as in 1D), and worked out some of its detailed consequences for two particles (Leinaas and Myrheim, 1977). They further pointed to the role of the fundamental group of the configuration space for arbitrary numbers of identical particles and the possibility for higher dimensional fibers (necessary for non-abelian representations, but they did not explicitly mention the braid group or its representation theory in their work).
2. **Algebraic:** In 1980–1981, starting out from the representation theory of the Lie algebra of local currents on $\mathbb{R}^d$ and the group of diffeomorphisms (akin to “Heisenberg quantization” and Dirac's canonical quantization scheme (Dirac, 1967)), Goldin, Menikoff, and Sharp found a kinematical derivation of the possibilities for quantum statistics with an unexpected dependence on the dimension d (Goldin et al., 1980, 1981). In Goldin et al. (1981) they also explored connections to the Aharonov–Bohm effect (in 3D) while subsequently in 1983, they highlighted the role of the one-dimensional unitary representations of the braid group (Goldin et al., 1983), and in 1985 pointed out that higher dimensional braid group representations induce inequivalent representations of the current algebra (Goldin et al., 1985). Such identical particles were later termed “plektons” (see, e.g., Dell'Antonio et al., 1997; Korff et al., 1999; Mund and Schrader, 1995) or simply “non-abelian anyons” (nowadays the more common term; cf., Nayak et al., 2008). It was also pointed out in Goldin et al. (1985) that nontrivial exchange phases in 2D do not require indistinguishability; the *colored* braid group serves as the fundamental group for configurations of *distinguishable* particles. The general algebraic (and potentially non-abelian) approach to quantum statistics was further developed in the field theory direction by Tsuchiya and Kanie (Tsuchiya and Kanie, 1987, 1988), Kohnno (Kohnno, 1987), as well as Fröhlich, Gabbiani, Kerler, and Marchetti (Fröhlich and Gabbiani, 1990; Fröhlich and Marchetti, 1988, 1989; Fröhlich, 1988, 1990; Fröhlich and Kerler, 1993), and Fredenhagen, Rehren, and Schroer (Fredenhagen et al., 1989).

Fig. 1 Three different perspectives on anyons.

3. **Magnetic:** In 1982, motivated by topological gauge theory examples in higher dimensions (“ θ -vacua” and “dyons”), Wilczek considered a composite of a 2D magnetic flux and a charged particle, coined for it the name “**anyon**,” as well as predicted its fractional spin and worked out the basic quantum mechanics for two such composite particles (Wilczek, 1982a, b). The same line of investigation was continued by Wu in 1984, who connected it to path integrals, extended it to arbitrary numbers of particles, and independently and explicitly invoked the braid group and its one-dimensional representations (Wu, 1984a, b). Further, Arovas, Schrieffer, Wilczek, and Zee considered in 1985 the statistical mechanics of a gas of such abelian anyons by means of its lowest order virial expansion (Arovas et al., 1985) (see also, Dowker, 1985).

The first concrete physical application of intermediate/fractional statistics and anyons came from the magnetic perspective and concerned the **fractional quantum Hall effect** (FQHE) (Laughlin, 1999; Stormer, 1999; Tsui, 1999), in which the emergent fractionally charged quasiparticles/holes introduced by Laughlin were proposed by Halperin to have such properties (Halperin, 1984). Arovas, Schrieffer, and Wilczek subsequently verified this (Arovas et al., 1984) (though under tacit assumptions of adiabaticity, Forte, 1991) by computing the corresponding Berry phase for quasiholes, thereby converging the geometric and magnetic (and eventually algebraic) perspectives. Further, the latent power of the algebraic perspective was brought to light in the new millennium as Kitaev proposed the usefulness of non-abelian anyons in topological quantum computation (Freedman et al., 2003; Kitaev, 2003, 2006). Most of the development of the field throughout this time span has been covered in the books and reviews (Canright and Johnson, 1994; Date et al., 2003; Forte, 1992; Fröhlich, 1990; Iengo and Lechner, 1992; Jackiw, 1990; Khare, 2005; Lerda, 1992; Myrheim, 1999; Nayak et al., 2008; Ouvry, 2007; Stern, 2008; Wilczek, 1990).

Precursor ideas

As is evident from the above, anyons and intermediate (“fractional”) quantum statistics are the convergence of many central ideas and concepts in mathematical physics. The former notion (anyon) is more closely tied into the concepts of **exchange phases** and symmetry classes of wave functions while the latter (fractional statistics) to that of the **exclusion principle** and permissible probability distributions for particles. It has been—and still is—a nontrivial task to rigorously connect these two notions in the strictly intermediate case (see, e.g., the review, Canright and Johnson, 1994). Exploration of intermediate statistics from the latter approach of exclusion with a finite occupation number of one-body states was considered by Gentile already in 1940–1942 (Gentile, 1940, 1942), and—inspired by anyons—another, dimension-independent, approach allowing for **fractional exclusion statistics** was suggested by Haldane in 1991 (Haldane, 1991).

Ideas of charged particles encircling regions of magnetic flux were developed by Ehrenberg and Siday (Ehrenberg and Siday, 1949), Aharonov and Bohm (Aharonov and Bohm, 1959), and the more general concept of geometric phases by Pancharatnam (Pancharatnam, 1956), Berry (Berry, 1984), and Simon (Simon, 1983). Methods of geometric quantization were developed by Souriau around 1967–1970, and he pointed out that if the configuration space is not simply connected, then more than two different group characters could arise and this “would lead to prequantizations of a new type” (Souriau, 1970). Around the same time, homotopy classes of Feynman paths brought another topological perspective on quantum statistics (Dowker, 1972; Laidlaw and DeWitt, 1971; Schulman, 1968) (cf., e.g., Mouchet, 2021). For example, Laidlaw and DeWitt remarked that possibilities in two space dimensions are not limited to bosons and fermions, but they did not elaborate further (Laidlaw and DeWitt, 1971).

Foundations for non-abelian anyons were laid much earlier in the theory of parastatistics (non-abelian representations of the permutation group) (Green, 1953; Messiah and Greenberg, 1964). Further, the central idea employed by Leinaas and Myrheim that equivalent configurations of indistinguishable particles need to be identified goes back all the way to Gibbs (cf., Fröhlich, 1990; Leinaas and Myrheim, 1977).

The above shows that the essential ideas that were necessary for the discoveries of anyons were floating around at the time, and it is also of interest to remark that, while it took about half a century from the discovery of bosons and fermions to that of anyons, it took another half a century to see their experimental confirmation.

Some remarks concerning one-dimensional anyons

Although this article concerns anyons in the 2D setting, it is unavoidable to note the influence of ideas from generalized notions of quantum statistics in 1D (i.e., $1 + 1$ spacetime dimensions). One of the first works in which generalized commutation relations for field operators can be found is Klaiber in 1968 (Klaiber, 1968), followed by Streater and Wilde (1970) and Fröhlich (1976). Transmutation of 1D hard-core bosons (studied classically by Tonks (1936)) into fermions and vice versa was considered by Girardeau (1960), who also noted topological and dimensional consequences for the configuration space (Girardeau, 1965). The Lieb–Liniger model (Lieb and Liniger, 1963) for point-interacting bosons in 1D constitutes the intermediate statistics found by Leinaas and Myrheim in 1D; however, exchange phases (thus “anyonic Lieb–Liniger”) may also be added to that model (Kundu, 1999). Leinaas and Myrheim later considered a different approach to statistics in 1D (and in higher dimensions) akin to “Heisenberg quantization” (Leinaas and Myrheim, 1993), and found a relationship to the Calogero–Sutherland model (Calogero, 1969a, b; Polychronakos, 1989; Sutherland, 1971). 2D anyons that are forced into the lowest Landau level of a strong magnetic field may be understood using such 1D concepts (Ouvry, 2007).

Key points

We will in this overview focus on providing answers to the following key questions:

1. How can the 2D anyon gas be defined physically and modeled mathematically?
2. What are the essential properties of the anyon gas? Does it admit some notion of exclusion statistics intermediate to bosons and fermions?
3. How can an anyon gas emerge in a realistic physical system consisting of only bosons and/or fermions?

The first question is addressed in the first part of Section “The ideal anyon gas” for the case of the ideal abelian anyon gas, and in the first part of Section “The nonideal anyon gas” for the nonideal abelian gas. Section “The non-abelian anyon gas” introduces the non-abelian gas in brief. The second question is the subject of the later parts of Sections “The ideal anyon gas,” “The nonideal anyon gas,” and “The non-abelian anyon gas.” The third and final question is addressed in Section “Emergence of the anyon gas.” Conclusions and an outlook are given in Section “Conclusion.”

The ideal anyon gas

Quantum statistics

The possibility for anyons in 2D boils down to the peculiar geometry and topology of the plane as compared to spaces of higher dimensions. Consider for simplicity two particles at positions $\mathbf{x}_1$ and $\mathbf{x}_2$ in the Euclidean plane $\mathbb{R}^2$, with a wave function Ψ encoding the probability density $|\Psi(\mathbf{x}_1, \mathbf{x}_2)|^2$ of observing the particles at these locations. An exchange of the two positions admits then a change in phase:

$$\Psi(\mathbf{x}_2, \mathbf{x}_1) = e^{\pm i\theta} \Psi(\mathbf{x}_1, \mathbf{x}_2),$$

where $\theta \in \mathbb{R}$. The sign is included above to specify the way in which the exchange is made, and if there is **orientation symmetry** then we cannot distinguish between clockwise and counterclockwise exchanges so that

$$e^{i\theta} = e^{-i\theta} \Leftrightarrow e^{2i\theta} = 1,$$

so $\theta/\pi \in \mathbb{Z}$ is either an even integer (bosons) or an odd integer (fermions). However, if we relax the assumption on orientation symmetry and consider a multivalued function for which we keep track of the number and orientation of elementary exchanges (the winding number), then we can allow *any* phase θ (anyons) to appear here. Conventionally, we write $\theta = \alpha\pi$ where α is known as the **statistics parameter** and can be either $\alpha \in \mathbb{R}$ (defined modulo periodicity 2) or in a suitable interval $\alpha \in (-1, 1]$ or $\alpha \in [0, 2)$; cf. Fig. 2.

More generally, we may consider a wave function Ψ for N **distinct particles** in d -dimensional Euclidean space $\mathbb{R}^d$ and its probability density:

$$|\Psi(\mathbf{x})|^2, \quad \mathbf{x} = (\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) \in \mathbb{R}^{dN} \setminus \Delta_N,$$

where, in order to indeed make them distinct, we have removed the (fat) **diagonal set** where any two or more particles overlap:

$$\Delta_N := \{\mathbf{x} \in \mathbb{R}^{dN} : \mathbf{x}_j = \mathbf{x}_k \text{ for some } j \neq k\}.$$

Our reason for considering distinct particles is that we, for simplicity at this stage, fix the particle number to N and assume that number to be certain and conserved (we shall return to possibilities of collisions on Δ_N later).

In the case where the particles are **identical** and thus **indistinguishable**, then we should reduce the configuration space further and ignore the (now artificial) labels:

$$X = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N\} \in \mathcal{C}^N := (\mathbb{R}^{dN} \setminus \Delta_N) / S_N,$$

where the permutation group S_N acts on the labels j of $\mathbf{x} = (\mathbf{x}_j)_{j=1}^N$ while leaving the equivalence class (set) X subject to this action fixed. Indeed, our N -particle configuration space is identical to the manifold

Fig. 2 The circle of abelian anyons, parametrized by the statistics parameter α . Note that any choice of proper anyons (i.e., neither bosons nor fermions) marks an additional point in this circle and thus breaks its orientation symmetry (mirror symmetry/complex conjugation).

$$\mathcal{C}^N = \{X = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N\} \subset \mathbb{R}^d : |X| = N\}$$

of all N -point subsets of $\mathbb{R}^d$. If we now consider exchanges of particles, then we can no longer act by permutations since it has lost meaning on configurations X of identical particles; however, what we can consider instead is the *continuous* exchange of positions in $\mathcal{C}^N$. Namely, among the continuous paths from a point $X \in \mathcal{C}^N$ to another point $Y \in \mathcal{C}^N$ there are the *loops*, starting and ending at the same point $X = Y$, which we hereby take to represent **continuous physical exchanges** of identical particles (Leinaas and Myrheim, 1977). Given such **exchange loops** σ (continuous functions $[0, 1] \rightarrow \mathcal{C}^N$ of a parameter, s.t. $\sigma(0) = \sigma(1)$), we may then consider lifting any wave function Ψ which has been assigned a value on a configuration $X \in \mathcal{C}^N$ to a multivalued function (More concretely, a section of a bundle with base space $\mathcal{C}^N$, or a ρ -equivariant function on the covering space of $\mathcal{C}^N$; see, for example, Dowker (1985), Fröhlich (1990), Mund and Schrader (1995), Dell'Antonio et al. (1997), Myrheim (1999), Lundholm (2019), and Lundholm and Qvarfordt (2020). The range/fiber is initially $\mathbb{C}$.) upon which the loops can act. Let us denote the action of a loop σ on Ψ at the point X by $\Psi(\sigma.X)$. Then we demand the **exchange conditions**

$$\Psi(\sigma.X) = \rho(\sigma)\Psi(X), \quad (1)$$

where $|\rho(\sigma)| = 1$ so that

$$|\Psi(\sigma.X)|^2 = |\Psi(X)|^2 \quad (2)$$

unambiguously defines a probability density at $X \in \mathcal{C}^N$. Further, $\rho(1) = 1$ for the trivial (constant) loop $\sigma = 1$, and if we compose two loops σ_1 and σ_2 into a new loop $\sigma_1\sigma_2$, then we demand the compatibility of the action,

$$\rho(\sigma_1\sigma_2) = \rho(\sigma_1)\rho(\sigma_2).$$

In other words, ρ is a group homomorphism and thus a **representation** of the group of exchange loops at X with composition.

In comparison, if we consider a single particle, $\mathcal{C}^{N=1} = \mathbb{R}^d$, charged and subject to magnetism, then the action of a path should be understood as the (parallel) transport of the charge along the path, and different loops σ may then give rise to different **holonomies** or phases given by the flux enclosed by the loop:

$$\rho(\sigma) = e^{i\Phi_\sigma}, \quad \Phi_\sigma = \oint_\sigma \mathbf{A} \cdot d\mathbf{r} = \int_{\text{interior of } \sigma} B(\mathbf{x}) d\mathbf{x},$$

where $\text{curl } \mathbf{A} = B$ is the magnetic field (viewed as a (pseudo)scalar field in $d = 2$ and appropriately projected in $d \geq 3$). However, for $N \geq 1$ and in the case that there is no external field so that $\rho(\sigma)$ should depend only on the topology of the loop σ , that is, if we require that $\rho(\sigma) = \rho(\sigma')$ for any two topologically equivalent loops $\sigma \sim \sigma'$ (connected by some continuous deformation), then we consider loops only up to homotopy and the relevant group of (equivalence classes of) loops is the **fundamental group** of the configuration space (Goldin et al., 1983, 1985; Wu, 1984a):

$$\sigma \in \pi_1(\mathcal{C}^N) = \begin{cases} \{1\}, & d = 1, \\ B_N, & d = 2, \\ S_N, & d \geq 3, \end{cases}$$

where B_N denotes the **braid group**, defined below. The group is trivial (Interesting statistics can still emerge as a choice of boundary condition on Δ_N (Leinaas and Myrheim, 1977).) in one dimension because particles then cannot exchange continuously without colliding, that is, hitting the diagonal set Δ_N .

Now, if Ψ takes values in $\mathbb{C}$, then $\rho(\sigma)$ is a phase—the **exchange phase** corresponding to the exchange loop σ —and we may identify different **exchange quantum statistics** as symmetry classes of Ψ defined by ρ in (1):

Bosons $\rho(\sigma) = +1$, the trivial representation. Wave functions Ψ extend symmetrically from $\mathcal{C}^N$ to $\mathbb{R}^{dN}$ (L^2 denotes the Hilbert space of square-integrable functions with inner product $\langle \Psi, \Phi \rangle = \int \overline{\Psi(\mathbf{x})} \Phi(\mathbf{x}) d\mathbf{x}$.),

$$L^2_{\text{sym}}(\mathbb{R}^{dN}) := \{\Psi \in L^2 : \Psi(\sigma.x) = \Psi(x), \sigma \in S_N\}$$

(the usual action of permutations, and with any missing data on Δ_N to be filled in, depending on our choice of Hamiltonian). For example, particles may be independent and identically distributed: $\Psi_0 = \otimes^N \psi_0 \in L^2_{\text{sym}}$,

$$\Psi_0(x) = (\otimes^N \psi_0)(x) = \prod_{j=1}^N \psi_0(\mathbf{x}_j),$$

corresponding to Bose–Einstein condensation in the single one-body state $\psi_0 \in L^2(\mathbb{R}^d)$.

Fermions $\rho(\sigma) = \text{sign}(\sigma) \in \{-1, +1\}$, the signed representation on S_N (signature of permutation). In this case wave functions Ψ extend *antisymmetrically* from $\mathcal{C}^N$ to $\mathbb{R}^{dN}$,

$$L^2_{\text{asym}}(\mathbb{R}^{dN}) := \{\Psi \in L^2 : \Psi(\sigma.x) = \text{sign}(\sigma)\Psi(x), \sigma \in S_N\}$$

(in this case it is natural to require that Ψ vanishes on $\triangle_N$). We apparently obtain determinantal correlations and the **Pauli principle** since functions in L^2_{asym} are spanned by **Slater determinants**, such as $\Psi_0 = \psi_0 \wedge \psi_1 \wedge \cdots \wedge \psi_{N-1}$, where

$$\bigwedge_{k=0}^{N-1} \psi_k(\mathbf{x}_1, \dots, \mathbf{x}_N) := \det \begin{bmatrix} \psi_0(\mathbf{x}_1) & \cdots & \psi_0(\mathbf{x}_N) \\ \vdots & & \vdots \\ \psi_{N-1}(\mathbf{x}_1) & \cdots & \psi_{N-1}(\mathbf{x}_N) \end{bmatrix}.$$

Anyons in $d = 2$ the most general ρ is a unitary representation of B_N . Proper anyons then correspond to those ρ which do not factor through S_N , that is, for which orientation symmetry is broken. Let us denote by L^2_ρ the Hilbert space of square-integrable multivalued wave functions Ψ based on the configuration space $\mathcal{C}^N$ and subject to the exchange conditions (1). A central question is, whether we can anticipate **intermediate or fractional exclusion statistics** in L^2_ρ ? Actually, it turns out that the information at hand is not sufficient to decide this, and even the above conclusions for bosons and fermions can be misleading, as we will see below.

The braid group

For $d = 2$, the group of continuous loops in $\mathcal{C}^N$ modulo homotopy is conveniently visualized as a group of N -particle world lines that evolve in $2 + 1$ -dimensional spacetime, subject to composition via some arbitrary but fixed reference configuration $X_0 \in \mathcal{C}^N$. The resulting group, denoted B_N , is the **braid group on N strands** (Artin, 1925, 1947; Birman, 1974):

$$B_N = \langle \sigma_1, \dots, \sigma_{N-1} : \sigma_j \sigma_{j+1} \sigma_j = \sigma_{j+1} \sigma_j \sigma_{j+1}, \sigma_j \sigma_k = \sigma_k \sigma_j \rangle_{\substack{j,k=1 \dots N-1 \\ k \neq j \pm 1}}$$

That is, the group generated by $N - 1$ elementary braids

$$\sigma_j : \begin{array}{c} | \quad | \quad | \quad | \quad | \\ 1 \quad 2 \quad \dots \quad j \quad \dots \quad N \end{array} \quad \sigma_j^{-1} : \begin{array}{c} | \quad | \quad | \quad | \quad | \\ 1 \quad 2 \quad \dots \quad j \quad \dots \quad N \end{array}$$

which are composed by stacking one on top of another. These elementary braids are subject to two sets of topological relations: one of which are known as the **Yang–Baxter relations**, and the other implement the commutativity of independent braids. In B_4 we have, for example,

$$\begin{array}{c} \text{Diagram 1: } \sigma_1 \sigma_2 \sigma_1 = \sigma_2 \sigma_1 \sigma_2 \\ \text{Diagram 2: } \sigma_3 \sigma_1 = \sigma_1 \sigma_3 \end{array}$$

If we add a third set of relations $\sigma_j^2 = 1 \forall j$, or equivalently, $\sigma_j = \sigma_j^{-1}$, that is, clockwise and counterclockwise exchanges cannot be distinguished, then we obtain the **permutation group** S_N . This will be the case for $d \geq 3$ since an elementary exchange may be rotated out of the plane (continuously and homotopically). From now on, we shall stick to the anyonic case $d = 2$.

If one looks for irreducible abelian unitary representations, that is, **exchange phases**

$$\rho : B_N \rightarrow \text{U}(1) = \{z \in \mathbb{C} : |z| = 1\},$$

then the Yang–Baxter relations single out a unique phase:

$$\rho(\sigma_j) = e^{i\alpha\pi}, \quad \text{for all } j = 1, 2, \dots, N - 1; \quad (3)$$

cf. Figs. 2 and 3. The only representations that factor through S_N require either $\alpha = 0$ ($\alpha \in 2\mathbb{Z}$) or $\alpha = 1$ ($\alpha \in 2\mathbb{Z} + 1$), thus corresponding to bosons or fermions. We will return to the non-abelian case, and representations with higher rank than 1, in Section “The non-abelian anyon gas.”

Fig. 3 Exchange loops for a single resp. a pair of particles with p other particles enclosed, and corresponding braid diagrams and phases. From Lundholm D and Solovej JP (2013a) Hardy and Lieb–Thirring inequalities for anyons. Communications in Mathematical Physics 322: 883–908

Kinetic energy

Above we considered wave functions $\Psi \in L^2_\rho$ that implement an exchange symmetry (1) by choice of a representation ρ of B_N . However, it turns out that this is only one part of the data that specifies an anyon model. The other, equally essential, part is the choice of a Hamiltonian or kinetic energy operator. Namely, in order to be able to consider continuous exchanges of particles we also need to resolve space and time at the appropriate energy scale.

Our starting point is the nonrelativistic (We remain nonrelativistic throughout this overview and likewise we will ignore spin; see however Jackiw (1990), Fröhlich (2009), and Mund (2009).) free kinetic energy for N particles with mass m :

$$T = \frac{1}{2m} \sum_{j=1}^N \mathbf{p}_j^2, \quad (4)$$

where $\mathbf{p}_j \in \mathbb{R}^2$ is the momentum of the particle with position $\mathbf{x}_j \in \mathbb{R}^2$. If the particles are all distinguishable, then the canonical quantization of this expression is obtained with momentum operators $\hat{\mathbf{p}}_j = -i\hbar \nabla_{\mathbf{x}_j}$ canonically conjugate to the position operators $\hat{\mathbf{x}}_j$, that is,

$$\hat{T}_{\text{dist}} := \frac{\hbar^2}{2m} \sum_{j=1}^N (-i\nabla_{\mathbf{x}_j})^2, \quad (5)$$

acting on (suitably regular) $\Psi \in L^2(\mathbb{R}^{2N})$.

In our case of identical anyons, we may consider the particles to be *locally* distinguishable. Namely, at any fixed point $X \in \mathcal{C}^N$, we may attach arbitrary labels to them:

$$\mathcal{C}^N \ni X = \{\mathbf{x}_1, \dots, \mathbf{x}_N\} \leftrightarrow (\mathbf{x}_1, \dots, \mathbf{x}_N) \in \mathbb{R}^{2N} \setminus \Delta_N,$$

and we can keep track of these labels along any paths from X in $\mathcal{C}^N$ as long as they cannot exchange nontrivially, that is, as long as any two possible paths do not compose to a topologically nontrivial loop. So in order to define free anyons, the idea is then that we should keep the kinetic energy operator as above whenever we consider wave functions Ψ supported on topologically trivial subsets of $\mathcal{C}^N$ (i.e., not encircling any of the holes in the manifold), which then can anyway be treated as subsets of the configuration space $\mathbb{R}^{2N} \setminus \Delta_N$ of distinguishable and distinct particles. Additional information must then be added to $\hat{T}_{\text{dist}}$ whenever we pass between different such subsets of $\mathcal{C}^N$ so as to complete topologically nontrivial loops $\sigma \in \pi_1(\mathcal{C}^N) = B_N$, $\sigma \neq 1$. One way to implement this concretely is to treat the exchange condition (1) as a topological boundary condition (Technically, Ψ is defined as a complex-valued function on the covering space of $\mathcal{C}^N$ subject to the ρ -equivariance condition (1), which is equivalent to regarding Ψ as a section of a complex line bundle over $\mathcal{C}^N$ with its geometry specified by $\rho: B_N \rightarrow \text{U}(1)$ (locally flat, but globally curved by the holonomies specified by $\rho(\sigma)$ for $\sigma \in B_N$); see, for example Dowker (1985), Mund and Schrader (1995), and Lundholm and Qvarfordt (2020).) that Ψ must satisfy in order to be in the domain of the operator, which we denote by

$$\hat{T}_\rho := \frac{\hbar^2}{2m} \sum_{j=1}^N (-i\nabla_{\mathbf{x}_j}^{(\rho)})^2, \quad (6)$$

or simply by $\hat{T}_\alpha$ if $\rho(\sigma_j) = e^{i\alpha\pi}$. For convenience we also denote the Hilbert space L^2_ρ by L^2_α in this case. Again, we stress that $\hat{T}_\alpha$ acts *locally* as the standard Laplacian $\hat{T}_{\text{dist}} = \frac{\hbar^2}{2m} \sum_{j=1}^N (-\Delta_{\mathbf{x}_j})$ on (suitably regular) $\Psi \in L^2_\alpha$, thus *independently* of α , but *globally* we have also the exchange conditions to account for, such as **pair exchange**

$$\Psi(\mathbf{x}_1, \dots, \mathbf{x}_{k'}, \dots, \mathbf{x}_j, \dots, \mathbf{x}_N) = e^{i(2p+1)\alpha\pi} \Psi(\mathbf{x}_1, \dots, \mathbf{x}_j, \dots, \mathbf{x}_{k'}, \dots, \mathbf{x}_N), \quad (7)$$

where p is the number of other particles enclosed in the exchange loop as $\mathbf{x}_j$ and $\mathbf{x}_{k'}$ are exchanged once in a counterclockwise manner (as well as other conditions; cf. Fig. 3).

As an example, consider the two-particle case $N = 2$ in center-of-mass and relative coordinates $\mathbf{X} = \frac{1}{2}(\mathbf{x}_1 + \mathbf{x}_2)$, $\mathbf{r} = \mathbf{x}_1 - \mathbf{x}_2$. Then the kinetic energy separates,

$$\hat{T}_\alpha = \frac{\hbar^2}{4m} (-\Delta_{\mathbf{X}}) + \frac{\hbar^2}{m} (-\Delta_{\mathbf{r}}), \quad (8)$$

and further, expressed in polar coordinates ($r = |\mathbf{r}|$, φ):

$$-\Delta_{\mathbf{r}} = -\partial_r^2 - \frac{1}{r} \partial_r - \frac{1}{r^2} \partial_\varphi^2. \quad (9)$$

These operators act on functions $\Psi(\mathbf{X}, r, \varphi)$ (here with its proper multivaluedness on $\mathcal{C}^2$ incorporated in the winding of $\varphi \in \mathbb{R}$ over multiples of π) such that

$$\Psi(\mathbf{X}, r, \varphi + \pi) = e^{i\alpha\pi} \Psi(\mathbf{X}, r, \varphi), \quad r > 0, \quad (10)$$

corresponding to the exchange condition (7) (all braids in B_2 are generated by this simple exchange σ_1). The manifold $\mathcal{C}^2$ may be parametrized by the set in $\mathbb{R}^4$ given by the half-space

$$\Omega = \{\mathbf{X} \in \mathbb{R}^2, r > 0, 0 \leq \varphi < \pi\},$$

and its boundary

$$\partial\Omega = \{\mathbf{X} \in \mathbb{R}^2, r = 0 \text{ or } \varphi = 0 \text{ or } \varphi = \pi\}$$

relates the two points ($r > 0, \varphi = 0$) and ($r > 0, \varphi = \pi$) topologically to the same point in $\mathcal{C}^2$. An equivalent description is therefore (8) and (9) defined on $L^2(\Omega)$ and subject to the boundary condition

$$\Psi(\mathbf{X}, r, \varphi = \pi) = e^{iz\pi} \Psi(\mathbf{X}, r, \varphi = 0), \quad r > 0.$$

The operator $\hat{T}_\rho$ as defined above is formally Hermitian but not self-adjoint (and not even necessarily *essentially* self-adjoint) since we have still not supplied any information at the diagonal set Δ_N , which cuts out holes of codimension 2 in the manifold $\mathcal{C}^N$ (for $N = 2$ this set is $\Delta_2 = \{\mathbf{X} \in \mathbb{R}^2, r = 0\}$). There is however a canonical choice of a self-adjoint realization (known in the mathematical literature as the **Friedrichs extension**) obtained by considering the expectation value of the kinetic energy in its formal quadratic form expression (This is more appropriately defined on $\mathcal{C}^N$ and observed to extend unambiguously to the covering space (Lundholm and Qvarfordt, 2020).)

$$\langle \Psi, \hat{T}_\rho \Psi \rangle = \frac{\hbar^2}{2m} \int_{\mathbb{R}^{2N}} \sum_{j=1}^N |\nabla_{\mathbf{x}_j}^{(\rho)} \Psi|^2 d\mathbf{x} \geq 0 \quad (11)$$

initially on (multivalued) wave functions Ψ that are smooth and compactly supported away from Δ_N and subject to the exchange conditions (7) resp. (1) (There is a natural extension (closure) of the energy form (11) to the largest subspace of the Hilbert space L^2_ρ upon which the energy is defined and finite, which is also the largest domain of the momentum operator $-i\nabla^{(\rho)}$. Denoting its adjoint $(-i\nabla^{(\rho)})^*$, one then defines $\hat{T}_\rho := \frac{\hbar^2}{2m} (-i\nabla^{(\rho)})^* (-i\nabla^{(\rho)})$, canonically self-adjoint on a corresponding smaller subspace of L^2_ρ . One might object that this approach seems to assume a **hard-core condition** on the anyons since functions are initially taken to vanish close to Δ_N ; however for bosons and fermions, this eventually yields exactly the standard free kinetic energy $\hat{T}_{\text{asym/sym}}$ (with the same expression as $\hat{T}_{\text{dist}}$) on the (Sobolev) spaces of anti/symmetric square-integrable functions with both one and two partial derivatives that are also square-integrable. It is in fact a peculiarity of dimensions $d \geq 2$ that any extra conditions at the diagonals disappear in this procedure so that our assumption on distinct particles is justified a posteriori; cf (Bourdeau and Sorkin, 1992; Lundholm and Solovej, 2014). This can also be understood by means of a more precise version of the Hardy inequality (34) discussed below (Lundholm and Qvarfordt, 2020).). For $N = 2$ the energy form (11) is

$$\langle \Psi, \hat{T}_\alpha \Psi \rangle = \frac{\hbar^2}{m} \int_{\mathbf{X} \in \mathbb{R}^2} \int_{r=0}^{\infty} \int_{\varphi=0}^{2\pi} \left(\frac{1}{4} |\nabla_{\mathbf{X}} \Psi|^2 + |\partial_r \Psi|^2 + \frac{1}{r^2} |\partial_\varphi \Psi|^2 \right) d\varphi r dr d\mathbf{X}, \quad (12)$$

again subject to the exchange condition (10). In general then, this specific choice of a self-adjoint operator $\hat{T}_\rho$ resp. $\hat{T}_\alpha$ is what we take to mean precisely by **free** (noninteracting, as compared to point-interacting; see below) **ideal anyons**, by analogy with bosons and fermions.

Statistics transmutation in 2D

So far we have worked exclusively in the geometric perspective of anyons, but we will now be able to make the connection to the magnetic perspective.

Since we have fixed our attention on the plane $\mathbb{R}^2$, it is occasionally convenient to switch to complex notation:

$$\mathbb{R}^{2N} \ni \mathbf{x} = (\mathbf{x}_1, \dots, \mathbf{x}_N) \leftrightarrow \mathbf{z} = (z_1, z_2, \dots, z_N) \in \mathbb{C}^N,$$

where the real (imaginary) part in $\mathbb{C}$ is canonically identified with the first (second) coordinate in $\mathbb{R}^2$.

Now, consider either a bosonic or a fermionic wave function $\Psi \in L^2_{\text{sym/asym}}(\mathbb{C}^N)$ restricted to the subset of distinct coordinates $\mathbf{z} \in \mathbb{C}^N \setminus \Delta_N$ and make there the gauge transformation $\Psi = U\tilde{\Psi}$, where

$$U(\mathbf{z}) := \prod_{j < k} \frac{z_j - z_k}{|z_j - z_k|} = \exp \left(i \sum_{j < k} \arg(z_j - z_k) \right), \quad (13)$$

the product of all relative phases of pairs of particles. One may verify that this expression is well defined and single valued on $\mathbb{C}^N \setminus \Delta_N$, unitary $|U(\mathbf{z})| = 1$, and antisymmetric w.r.t. permutations of labels in $\mathbf{z} = (z_j)_{j=1}^N$ so that if Ψ is symmetric, then $\tilde{\Psi} = U^{-1}\Psi$ is antisymmetric and vice versa. Thus, modulo the smaller set of diagonals Δ_N where it is not defined, the unitary

transformation by U achieves a **statistics transmutation** $L_{\text{sym}}^2 \leftrightarrow L_{\text{asym}}^2$ between bosons and fermions in 2D. This perhaps seems confusing, however, recall that the kinetic energy is equally important in defining the exchange statistics. Indeed, if we consider the momentum then this transmutation comes at the cost of a **gauge potential**:

$$-i\nabla_{\mathbf{x}_j}\Psi = U(-i\nabla_{\mathbf{x}_j} + \mathbf{A}_j)\tilde{\Psi}, \quad (14)$$

where we have defined the vector potentials

$$\mathbf{A}_j(\mathbf{x}) := -iU^{-1}\nabla_{\mathbf{x}_j}U = \sum_{k \neq j} \frac{(\mathbf{x}_j - \mathbf{x}_k)^\perp}{|\mathbf{x}_j - \mathbf{x}_k|^2}, \quad (15)$$

for $j = 1, \dots, N$, and we denoted a $\pi/2$ rotation in $\mathbb{R}^2$

$$\mathbf{x} = (x, y) \mapsto \mathbf{x}^\perp = (-y, x)$$

(or $z \mapsto iz$). In other words, if we had initially

$$\hat{T}_{\text{asym}} = \frac{\hbar^2}{2m} \sum_{j=1}^N (-i\nabla_{\mathbf{x}_j})^2 \quad \text{acting on } L_{\text{asym}}^2,$$

then we now obtain

$$\hat{T}_{\text{sym} \rightarrow \text{asym}} := \frac{\hbar^2}{2m} \sum_{j=1}^N (-i\nabla_{\mathbf{x}_j} + \mathbf{A}_j)^2 \quad \text{acting on } L_{\text{sym}}^2,$$

so that indeed fermions may be represented as bosons, although with an additional magnetic interaction. The magnetic field seen by particle j ,

$$\text{curl}_{\mathbf{x}_j} \mathbf{A}_j = 2\pi \sum_{k \neq j} \delta(\mathbf{x}_j - \mathbf{x}_k), \quad (16)$$

corresponds to the attachment of **Aharonov–Bohm point fluxes** of magnitude 2π to each of the other particles. The set where this field is singular is precisely $\triangle_N$.

Similarly, if we fix a statistics parameter $\alpha \in \mathbb{R}$ and consider $\Psi = U^\alpha \tilde{\Psi}$ (now typically a singular gauge transformation involving multivalued functions over $\mathbb{C}^N \setminus \triangle_N$), then

$$-i\nabla_{\mathbf{x}_j}\Psi = U^\alpha(-i\nabla_{\mathbf{x}_j} + \alpha\mathbf{A}_j)\tilde{\Psi}, \quad (17)$$

and thus if we originally had the anyonic kinetic energy

$$\hat{T}_\alpha = \frac{\hbar^2}{2m} \sum_{j=1}^N (-i\nabla_{\mathbf{x}_j})^2 \quad \text{acting on } \Psi \in L_\alpha^2,$$

then we obtain an equivalent description in terms of bosons:

$$\hat{T}_{\text{sym} \rightarrow \alpha} := \frac{\hbar^2}{2m} \sum_{j=1}^N (-i\nabla_{\mathbf{x}_j} + \alpha\mathbf{A}_j)^2, \quad \text{acting on } \tilde{\Psi} \in L_{\text{sym}}^2.$$

If we instead consider the transformation $\Psi = U^{\alpha-1}\tilde{\Psi}$ where $\tilde{\Psi} \in L_{\text{asym}}^2$, then we arrive at a description in terms of fermions:

$$\hat{T}_{\text{asym} \rightarrow \alpha} := \frac{\hbar^2}{2m} \sum_{j=1}^N (-i\nabla_{\mathbf{x}_j} + (\alpha-1)\mathbf{A}_j)^2,$$

acting on L_{asym}^2 . The magnetic field of $\alpha\mathbf{A}_j$ corresponds to the attachment of Aharonov–Bohm fluxes of magnitude $2\pi\alpha$ to each of the other particles. In this way we have the freedom to treat anyons as either bosons or fermions with topological magnetic interactions. This tool can certainly be beneficial as we can trade a simple operator (the free kinetic energy) but on a complicated geometry (multivalued functions with appropriate exchange conditions), for a complicated operator (magnetic interactions) but on a simple geometry (symmetric or antisymmetric functions on $\mathbb{R}^{2N}$). The former choice is usually referred to as the **anyon gauge** while the latter is the **magnetic gauge**, and this connection also brings us from an idealized world of quantum statistics of point particles and closer to the various possibilities for emergent statistics transmutation phenomena.

The procedure we referred to above to ensure the self-adjointness of the kinetic energy operator by extending the energy form (Friedrichs extension) also applies in this magnetic gauge formulation of the problem so that indeed the operators $\hat{T}_{\text{sym/asym} \rightarrow \alpha}$ are self-adjoint on appropriate domains in $L_{\text{sym/asym}}^2$ where the energy is finite (Lundholm and Solovej, 2014). Further, we remark that multiples of the unitary multiplication operator

$$U^2 : L_{\text{sym/asym}/\alpha}^2 \rightarrow L_{\text{sym/asym}/(\alpha+2)}^2$$

may be used, together with complex conjugation symmetry, to obtain that the free ideal anyonic kinetic energies are unitarily equivalent w.r.t. the transformations

$$\alpha \mapsto \alpha + 2n, \quad n \in \mathbb{Z} \quad \text{and} \quad \alpha \mapsto -\alpha. \quad (18)$$

Exchange vs. exclusion

Now that we have managed to define more or less concrete but still hypothetical models for ideal abelian anyons, we come to the next question: How do such anyons actually behave? If we are ever to observe them in nature then we need to know their behavior. So, are they more like bosons or more like fermions, or something in between, like the terms “intermediate statistics” or “fractional statistics” suggest? In other words, can we in any way relate the intermediate (braid) **exchange statistics** encoded into anyons to some intermediate **exclusion statistics** concerning the occupation numbers of various states as seen from a one-body perspective. Of course, since the magnetic gauge picture clarifies that anyons are (possibly) at least as complicated as strongly interacting systems of bosons or fermions, it is a priori not at all obvious whether this is possible. The issue of exchange vs. exclusion was referred to as “ α to β ” by Canright and Johnson in their review (Canright and Johnson, 1994) on the matter.

Only in cases of very few particles, $N = 2, 3, 4$, are energy spectra for ideal anyons well understood because they have then been computed analytically (for $N = 2$ (Arovas et al., 1985; Leinaas and Myrheim, 1977; Wilczek, 1982b), also extending to a collective (Date and Murthy, 1993; Date et al., 2003) part of the spectrum for all N (Chou, 1991; Wu, 1984b)) or numerically (the remaining part of the spectrum (Murthy et al., 1991; Sporre et al., 1991, 1992)), in a few situations.

In order to lift the degeneracy of the spectrum and facilitate comparison, it is convenient to confine the particles in a harmonic trapping potential $V(\mathbf{x}) = \frac{1}{2}m\omega^2|\mathbf{x}|^2$. For N anyons in the magnetic gauge description w.r.t. bosons, we thus consider the Hamiltonian operator

$$\hat{H}_N = \hat{T}_{\text{sym} \rightarrow \alpha} + \hat{V} = \sum_{j=1}^N \left[\frac{\hbar^2}{2m} (-i\nabla_{\mathbf{x}_j} + \alpha \mathbf{A}_j)^2 + V(\mathbf{x}_j) \right],$$

and its corresponding ground-state energy (g.s.e.)

$$E_N := \inf \text{spec } \hat{H}_N = \inf_{0 \neq \Psi \in L^2_{\text{sym}}} \langle \hat{H}_N \rangle_{\Psi}, \quad (19)$$

where $\langle \hat{A} \rangle_{\Psi} := \langle \Psi, \hat{A} \Psi \rangle / \langle \Psi, \Psi \rangle$ denotes the expectation of any operator $\hat{A}$ in a state $\Psi \neq 0$. The spectrum of the 2D harmonic oscillator $\hat{H}_{N=1}$ is well known:

$$\text{spec } \hat{H}_1 = \{\hbar\omega n\}_{n=1,2,3,\dots} \quad (\text{each with multiplicity } n),$$

and for bosons one thus obtains N times the lowest eigenvalue, $E_N(\alpha = 0) = \hbar\omega N$, while for (spinless) fermions, due to the Pauli principle, we must sum over the N first eigenvalues according to their multiplicity: $E_N(\alpha = 1) \sim \frac{\sqrt{8}}{3} \hbar\omega N^{3/2}$ as $N \rightarrow \infty$. Further, because of rotation symmetry, the Hamiltonian commutes with the total angular momentum operator

$$\hat{L}/\hbar = -i \sum_{j=1}^N [x_j \partial_{y_j} - y_j \partial_{x_j}] = \sum_{j=1}^N \left[z_j \frac{\partial}{\partial z_j} - \bar{z}_j \frac{\partial}{\partial \bar{z}_j} \right],$$

and its eigenvalues $L \in \mathbb{Z}$ can therefore be used to separate the energy spectrum further.

The spectrum of $\hat{H}_N$ for $N = 2$ and $N = 3$ is shown in Fig. 4, and while in the former case it manifests a strictly linear interpolation between bosons and fermions (Leinaas and Myrheim, 1977)

$$E_2(\alpha) = \hbar\omega \left(2 + \min_{q \in \mathbb{Z}} |2q + \alpha| \right), \quad (20)$$

in the latter case there are also nonlinearly interpolating states at various L , and such a state with $L \neq 0$ comes down from an excited level at $\alpha = 0$ to reach the Fermi energy at $\alpha = 1$. Similar features are also seen in the numerical spectrum for $N = 4$ (Sporre et al., 1992) and expected to occur for all $N \geq 3$ (Chitra and Sen, 1992).

Rough upper bounds for E_N at any α and N are obtained simply by considering trial states that localize the particles on separate domains in $\mathbb{R}^2$ so that their exchange statistics is not seen (in the magnetic gauge picture one may then gauge away all magnetic interactions while in the anyon gauge picture, one then stays within a domain of distinguishability). By balancing the localization energy and the spread into the potential one then finds that $E_N(\alpha) \lesssim \hbar\omega N^{3/2}$, that is, the energy is at most at the order of fermions. Note however that the fermionic energy does not provide a strict upper bound, as seen for $N = 3$ where $E_3(\alpha \approx 0.7) > E_3(\alpha = 1)$.

On the other hand, it is also useful to note that the bosonic energy, for which the g.s. Ψ_0 is a Gaussian at the origin $\mathbf{x} = 0$, always gives a rigorous lower bound:

$$E_N(\alpha) \geq E_N(0) = \hbar\omega N, \quad (21)$$

Fig. 4 Energy spectra for $N=2$ (upper) and $N=3$ (lower) anyons in a harmonic trap (minus the center of mass energy 1, and in suitable units). From Yakaboylu E, Ghazaryan A, Lundholm D, Rougerie N, Lemeshko M, and Seiringer R (2020) Quantum impurity model for anyons. *Physical Review B* 102: 144109; cf. also Leinaas JM and Myrheim J (1977) On the theory of identical particles. *Nuovo Cimento B* 37: 1–23; Murthy MVN, Law J, Brack M, and Bhaduri RK (1991) Quantum spectrum of three anyons in an oscillator potential. *Physical Review Letters* 67: 1817–1820; and Sporre M, Verbaarschot JJM, and Zahed I (1991) Numerical solution of the three-anyon problem. *Physical Review Letters* 67: 1813–1816

since the kinetic energy satisfies a **diamagnetic inequality** (Lundholm and Solovej, 2014)

$$\langle \hat{T}_\alpha \rangle_\Psi \geq \langle \hat{T}_{\text{sym}} \rangle_{|\Psi|}. \quad (22)$$

This is observed by factoring Ψ into its modulus and phase, and dropping the phase contribution to the momentum $-i\nabla \Psi$.

Chitra and Sen (1992) provided a more interesting lower bound to the spectrum for any N , extending (20): for an arbitrary state Ψ with angular momentum L , it holds

$$\langle \hat{H}_N \rangle_\Psi \geq \hbar\omega \left(N + \left| L + \alpha \frac{N(N-1)}{2} \right| \right). \quad (23)$$

Combined with our a priori upper bound, this implies that in the ground state the angular momentum needs to be close to

$$L \approx -\alpha \binom{N}{2} \text{ since } \left| L + \alpha \binom{N}{2} \right| \lesssim O(N^{3/2}) \quad (24)$$

so that on the average, there needs to be an angular momentum $-\alpha$ for every pair of particles in order to cancel the shifted inherent/anyonic angular momentum (the number of attached units of magnetic flux per particle). This also means that as N grows large, there will be a large number $O(N^{1/2})$ of level crossings in the g.s. between different integer angular momenta because any fixed angular momentum L can only be good on a scale $\Delta\alpha = O(N^{-1/2})$. The situation is sketched in Fig. 5, where at fixed $N \gg 1$, one expects to find curves corresponding to families of states at fixed L that are smoothly varying with α , to eventually come down to an energy $O(N^{3/2})$ on a $O(N^{1/2})$ -neighborhood around a suitable minimum $\alpha \approx \alpha_0(L)$, and then to again shoot upwards in energy with a slope $\gtrsim O(N^2)$.

Fig. 5 Schematic energy spectrum for $N \gg 1$ (left) and estimates for the g.s.e. near bosons and fermions (right) for anyons with statistics $\alpha = \theta/\pi$ in a harmonic trap. From Chitra R and Sen D (1992) Ground state of many anyons in a harmonic potential. Physical Review B 46: 10923–10930

Chitra and Sen went on to estimate (again, see Fig. 5) the enveloping g.s.e. curve close to bosons (suggesting $E_N/(\hbar\omega N^{3/2}) \approx \frac{7\sqrt{3}}{9}\sqrt{\alpha}$) and to fermions (suggesting $E_N/(\hbar\omega N^{3/2}) \approx \frac{\sqrt{8}}{3}$), but left it as an open problem whether there are nonanalyticities in the limiting function

$$h(\alpha) := \liminf_{N \rightarrow \infty} E_N(\alpha)/(\hbar\omega N^{3/2}), \quad (25)$$

concluding that “This is an interesting but difficult question to answer.”

Toward density functionals for anyons

The few-particle spectra led to some initial results on the thermodynamics of the anyon gas, by considering the high-temperature, low-density virial expansions (Arovas et al., 1985; Dowker, 1985) (see Khare, 2005; Mancarella et al., 2013b; Myrheim, 1999, for review). In the low-temperature regime, in order to make the many-anyon ground-state problem more manageable, we could wish for a limiting effective description with a relatively limited number of degrees of freedom that are sufficient to describe the collective state of the system at $N \rightarrow \infty$. Such a state might converge toward the minimizer of a suitable functional, that is, (taking some suitable scale $a > 0$ for normalization):

$$E_N/N^a \xrightarrow{N \rightarrow \infty} \text{minimum of } \mathcal{E}[\psi] \text{ or } \mathcal{E}[\varrho], \text{ and} \\ \text{some marginal of g.s. } \Psi_0 \text{ of } \hat{H}_N \xrightarrow{N \rightarrow \infty} \text{minimizer of } \mathcal{E},$$

where $\mathcal{E}$ is typically an energy functional of either one-body states $\psi \in L^2(\mathbb{R}^2)$ or of corresponding probability densities $\varrho = |\psi|^2 \in L^1(\mathbb{R}^2)$ (with mass 1 or N).

For example, for 2D fermions in a trapping potential V , one has the **Thomas–Fermi approximation** (Fermi, 1927; Thomas, 1927):

$$E_N = \inf_{0 \neq \Psi \in L^2_{\text{asym}}} \langle \hat{T}_{\text{asym}} + \hat{V} \rangle_{\Psi} \approx \inf_{\varrho \geq 0: \int_{\mathbb{R}^2} \varrho = N} \mathcal{E}^{\text{TF}}[\varrho], \quad (26)$$

where the density $\varrho = \varrho^{\text{TF}} \approx \varrho_{\Psi_0}$ (one-body marginal of g.s.) minimizes the **Thomas–Fermi (TF) functional**

$$\mathcal{E}^{\text{TF}}[\varrho] := \int_{\mathbb{R}^2} [2\pi\varrho(\mathbf{x})^2 + V(\mathbf{x})\varrho(\mathbf{x})] d\mathbf{x}. \quad (27)$$

(Note: To simplify our discussion, we shall now and in the remainder of this article assume that the physical constant $\hbar^2/(2m) = 1$, that is, $T = \mathbf{p}^2$, by an appropriate choice of units $\hbar = 2m = c = e = 1$.) The kinetic energy density is here given by the energy per unit area of the **homogeneous 2D Fermi gas** at density $\varrho(\mathbf{x})$, obtained, for example, by confining N fermions in a box of area $L \times L$, summing the one-body eigenvalues and taking the thermodynamic limit:

$$E_N/L^2 \xrightarrow{N, L \rightarrow \infty} 2\pi\bar{\varrho}^2, \quad \text{at fixed } \bar{\varrho} = N/L^2.$$

On the other hand, for bosons with sufficiently weak *scalar* interactions, one has the **Gross–Pitaevskii (GP) functional** (Gross, 1961; Pitaevskii, 1961):

$$\mathcal{E}^{\text{GP}}[\psi] := \int_{\mathbb{R}^2} [|(-i\nabla + \mathbf{A}_{\text{ext}})\psi|^2 + V|\psi|^2 + g|\psi|^4], \quad (28)$$

describing approximate condensation into the state $\psi \in L^2(\mathbb{R}^2)$ as $E_N/N \rightarrow \text{minimum of } \mathcal{E}^{\text{GP}}$. In regimes where the interaction strength $g \in \mathbb{R}$ (related to the scattering length of the interaction potential) dominates over the kinetic term, one may neglect that term and keep only the last two terms, again leaving a functional of $\varrho = |\psi|^2$ of the Thomas–Fermi type with $g \leftrightarrow 2\pi N$ (this is only a formal analogy at the level of functionals since the two mechanisms of the approximations are very different).

In view of the above, could one then suggest the following interpolating functional for $0 < \alpha \leq 1$, describing an “**average-field**” approximation for anyons

$$\mathcal{E}^{\text{af}}[\varrho] \approx \int_{\mathbb{R}^2} [2\pi\alpha\varrho(\mathbf{x})^2 + V(\mathbf{x})\varrho(\mathbf{x})] d\mathbf{x} \quad ? \quad (29)$$

Indeed, in a mean-field (We differentiate between “average-field” and “mean-field,” partly to distinguish the anyonic context but also because of more technical reasons that will be clarified below.) (**Hartree**) ansatz for the ground state in the bosonic representation, consider:

$$\Psi(\mathbf{x}) = \psi(\mathbf{x}_1)\psi(\mathbf{x}_2) \dots \psi(\mathbf{x}_N), \quad (30)$$

and we may think of a single particle $\psi \in L^2(\mathbb{R}^2)$ in the magnetic field of the others (identically distributed):

$$B(\mathbf{x}) \approx 2\pi\alpha(N-1)|\psi(\mathbf{x})|^2 \approx 2\pi\alpha\varrho_\Psi(\mathbf{x}). \quad (31)$$

If the density $\varrho_\Psi = N|\psi|^2$ is approximately constant on an area $L \times L$ where N bosons condense into the lowest Landau level of the field B (cf. (64) below), then one indeed obtains an energy per unit area

$$E_N/L^2 \approx BN/L^2 \approx 2\pi\alpha\bar{\varrho}^2, \quad \bar{\varrho} = N/L^2, \quad (32)$$

thus suggesting (29). For the ideal anyon gas, this argument is not rigorous, because one cannot apply such an ansatz in the singular magnetic field (it is not in the appropriate domain of $\hat{T}_\alpha$). This difficulty can be overcome using regularization, however, and we return to it in Section “Almost-bosonic anyons” in conjunction with the extended anyon gas. Thus, after accepting some refinements to the “average-field” approach in that context, it has been successfully applied in the limits $\alpha \rightarrow 0$ and $\alpha \rightarrow 1$ as $N \rightarrow \infty$.

To be precise, if we wish to refer to the approximation as above with an almost constant field (on the scale of a trap), then it is perhaps more appropriate to call it a “**constant-field**” approximation. We also note that if (29) would be a valid description for proper anyons, then it suggests that for the harmonic oscillator problem

$$E_N \stackrel{?}{\approx} \inf_{\substack{\varrho \geq 0 \\ \int \varrho = N}} \int_{\mathbb{R}^2} \left[\frac{\hbar^2 \pi \alpha}{m} \varrho(\mathbf{x})^2 + \frac{m\omega^2}{2} |\mathbf{x}|^2 \varrho(\mathbf{x}) \right] d\mathbf{x} = \frac{\sqrt{8}}{3} \sqrt{\alpha} \hbar \omega N^{3/2}, \quad 0 < \alpha \leq 1. \quad (33)$$

Early applications of variants of **density functional theory** (DFT) to the anyon context were made by Chitra and Sen, who proposed the refinement as in Fig. 5 due to the bosons’ hard core (Chitra and Sen, 1992), and by Li, Bhaduri and Murthy who considered an extension of TF theory to excited states in the spectrum (Li et al., 1992). Again, only some aspects have been rigorously justified, in the limits close to bosons and fermions.

Local exclusion principle and degeneracy pressure for the ideal anyon gas

An approach that has been successful for an increased qualitative understanding of the genuine ideal anyon gas at arbitrary α is to take a strictly *local* route to exclusion via the wider concept of **statistical repulsion**. Namely, one may note that statistical repulsion manifests itself in the anyon gas in (at least) three ways:

1. **Effective scalar pairwise repulsion.** The exchange conditions (7) for each pair of particles transpire to yield a pair repulsion between particles. Its simplest form can be stated as a lower bound (known in mathematics as a many-particle **Hardy inequality**, Hoffmann-Ostenhof et al., 2008; Lundholm and Solovej, 2013a) for the kinetic energy: for any N ,

$$\hat{T}_\alpha \geq \frac{4\alpha_N^2}{N} \sum_{j < k} \frac{1}{|\mathbf{x}_j - \mathbf{x}_k|^2}, \quad (34)$$

interpreted in the sense of forms or expectation values, and where the so-called N -fractionality of α , defined

$$\alpha_N := \min_{p=0,1,\dots,N-2} \min_{q \in \mathbb{Z}} |(2p+1)\alpha - 2q|,$$

is the arcwise distance (in units of π) on the unit circle from the set $\{e^{i(2p+1)\alpha\pi}\}_{p=0,1,\dots,N-2}$ of all possible pair-exchange phases to the point $+1$ of bosons. Taking the limit as $N \rightarrow \infty$ one finds (see Fig. 6)

$$\alpha_{N \rightarrow \infty} = \begin{cases} \frac{1}{v}, & \text{if } \alpha = \frac{\mu}{v} \text{ odd-numerator reduced rational,} \\ 0, & \text{otherwise,} \end{cases} \quad (35)$$

an odd variant of Thomae's "popcorn function."

The origin of the scalar lower bound (34) lies in the effective angular momentum barrier of each pair of particles at distance $r > 0$:

$$V_{\text{stat}}(r) = |(2p+1)\alpha - 2q|^2 \frac{1}{r^2} \geq \frac{\alpha_N^2}{r^2}. \quad (36)$$

Namely, in an exchange of two particles, as in (7) where p other particles happen to be ensnared, an anyonic phase shift $e^{i(2p+1)\alpha\pi} \neq 1$ leaves a residual angular momentum according to (36). Heuristically, we can anticipate this effect in the two-particle energy form (12), where the quantization condition (10) in the angular variable φ is appropriately modified to account for the presence of any extra particles, assuming all other position variables are fixed and the relative angular variable undergoes a full loop $\varphi \rightarrow \varphi + \pi$ in configuration space. The anyonic phase then shifts the relative angular momentum of the pair, which however is quantized over the even integers due to the half-circle symmetry for identical particles (The operator $\hat{\ell} = -i\partial_\varphi$ on $[0, \pi]$ with twisted boundary conditions $\psi(\pi) = e^{i\alpha\pi}\psi(0)$ has eigenvalues $\{\alpha - 2q\}_{q \in \mathbb{Z}}$. Therefore the minimum of ℓ^2 is $\min_{q \in \mathbb{Z}} |\alpha - 2q|^2 = \alpha_N^2$. Compare also (20).).

We expect the repulsive barrier (36) to be stronger than the r.h.s. on average as the number p fluctuates. Indeed, the coupling constant of the pair-interaction potential on the r.h.s. of (34) can be strengthened to a nearest-neighbor version, which only depends on the 2-fractionality α_2 (periodized α), if it is at the same time weakened by yet another factor of N (Lundholm and Qvarfordt, 2020; Rougerie and Yang, 2022). Anyway, the repulsion offered by the potential is strong enough to imply that $\Psi \rightarrow 0$ at $\triangle_N$ if $\alpha_2 \neq 0$, and can therefore be viewed as a **generalized Pauli principle** for anyons (Lundholm, 2017; Lundholm and Qvarfordt, 2020; Lundholm and Solovej, 2013b) (other variants were considered in Fröhlich and Marchetti (1988, 1989), Goldin and Sharp (1996), and Goldin and Majid (2004)).

2. Local exclusion principle. The bound (34) (with its various refinements Larson and Lundholm, 2018; Lundholm and Qvarfordt, 2020; Lundholm and Solovej, 2013a) can also be applied locally on subsets of the plane and is strong enough to yield a linear bound $E_N \gtrsim N - 1$ for the local (Neumann) energy (Lundholm and Seiringer, 2018; Lundholm and Solovej, 2013b). Again, this holds modulo a (positive) constant that either depends on α_N , or a typically weaker one (still positive) that only depends on α_2 (cf. Fig. 7).

Fig. 6 ∞ -Fractionality of α given by the odd popcorn function (35) (Lundholm, 2017; Lundholm and Solovej, 2013a).

Fig. 7 Lower bounds to the homogeneous ideal anyon gas energy (Larson and Lundholm, 2018; Lundholm and Seiringer, 2018). The blue points are numerical lower bounds for $E_2(\alpha) = 4\pi\alpha + O(\alpha^{4/3})$ at $\alpha = \alpha_{N \rightarrow \infty}$ while the orange curve describes $F_2(\alpha_2) = \frac{1}{4} \min\{E_2(\alpha_2), 0.147\}$, correspondingly.

For comparison, take, for example, the unit square $Q = [0, 1]^2$ and consider fermions which there satisfy the bound

$$E_N(\alpha = 1, Q) \geq \pi^2(N - 1) \quad \text{for } N \geq 1, \quad (37)$$

since each added particle is orthogonal to the ground state (the constant function) and thus adds at least the energy $E_2 = \pi^2$ of a first-excited state $\psi(x, y) \propto \cos(\pi x)$ or $\cos(\pi y)$.

For anyons, we denote the N -particle **Neumann energy on Q** by

$$E_N(\alpha, Q) := \inf_{0 \neq \Psi \in L^2_{\text{sym}}(Q^N)} \langle \hat{T}_{\text{sym} \rightarrow \alpha} \rangle_{\Psi}. \quad (38)$$

It is known that (Larson and Lundholm, 2018; Lundholm and Seiringer, 2018)

$$E_2(\alpha, Q) = 4\pi\alpha_2 + O(\alpha_2^{4/3}) \quad \text{for any } \alpha, \quad (39)$$

and furthermore, all higher particle energies can be bounded uniformly in terms of this energy, or a suitable approximation ($\tilde{E}_2(\alpha) \approx 2\pi(j'_{\alpha_2})^2 \geq 4\pi\alpha_2$, where j'_α denotes the first zero of the derivative of the Bessel function J_α (Larson and Lundholm, 2018).) $\tilde{E}_2$ to it: for $N \geq 2$,

$$E_N \geq (N - 1)\tilde{E}_2(\alpha_N), \quad (40)$$

as well as

$$E_N/N \geq \frac{1}{4} \min\{E_2, E_3, E_4\} \geq \frac{1}{4} \min\{E_2(\alpha_2), 0.147\}. \quad (41)$$

This r.h.s. we denote by $F_2(\alpha_2)$; cf. Fig. 7. An interpretation of the above is that the nearest-neighbor energy E_2 is a relatively good approximation at every scale (at least as a lower bound) due to a balancing of uncertainty and exclusion in the gas.

3. Degeneracy pressure. Lastly, a combination of the above local exclusion principle and the uncertainty principle (also in a local formulation) yields a convenient measure of the degeneracy pressure in the anyon gas.

Compare the TF functional (27), which shows that the effect of the exclusion principle for fermions is a self-energy for the density that penalizes localization and thus forces a spread of the profile into the more expensive regions of the trapping potential. Indeed, the ideal Fermi gas satisfies the following kinetic energy inequality (known in mathematics as a **Lieb–Thirring inequality** (Lieb and Thirring, 1975)) which captures this type of degeneracy pressure: for any number N of particles and any N -fermion state $\Psi \in L^2_{\text{asym}}(\mathbb{R}^{2N})$,

$$\langle \hat{T}_{\text{asym}} \rangle_{\Psi} \gtrsim \int_{\mathbb{R}^2} \varrho_{\Psi}(\mathbf{x})^2 d\mathbf{x} \quad (42)$$

(modulo a universal constant (Deciding on the best constant in this inequality is a long-standing open problem, but it is conjectured (Lieb and Thirring, 1976) to be given by that of its restriction to $N = 1$ (a Sobolev constant) and is strictly smaller than the TF constant 2π . See Seiringer and Solovej (2023) for recent progress.)), where ϱ_{Ψ} is the one-body density associated to Ψ , obtained by marginalizing $N - 1$ particles. Inequalities of this type have been useful to prove qualitative properties of large fermionic systems such as their thermodynamic stability w.r.t. Coulomb interaction with a mixture of charges (Dyson and Lenard, 1967; Lieb and Seiringer, 2010; Lieb and Thirring, 1975). In the case that v species of fermions or spin states are considered, the constant in (42) is weakened by a factor $1/v$.

The degeneracy pressure for anyons is measured by a similar inequality (Lundholm and Solovej, 2013a, b) (see Lundholm and Qvarfordt (2020) for review): for any number N of particles and any N -anyon state $\Psi \in L^2_\alpha$,

$$\langle \hat{T}_\alpha \rangle_\Psi \gtrsim \alpha_2 \int_{\mathbb{R}^2} \varrho_\Psi(\mathbf{x})^2 d\mathbf{x} \quad (43)$$

(again modulo a universal constant). Its strength thus depends on leading order of the 2-fractionality, that is, the nearest-neighbor exchange statistics α . It then follows, like for fermions, that charged anyonic systems (except bosons) with Coulomb interaction are also stable (Lundholm and Seiringer, 2018; Lundholm and Solovej, 2014).

Applied to the harmonic trap (19), the degeneracy pressure (43) yields the bound

$$E_N(\alpha, \text{harm. osc.}) \gtrsim \sqrt{\alpha_2} \hbar \omega N^{3/2}, \quad (44)$$

which indeed matches the constant-field approximation (33), and Fig. 5, up to the value of the universal constant.

On a disk geometry D with unit area, the analysis of Chitra and Sen again suggests a large number of level crossings as $N \rightarrow \infty$, and thus possibly nonanalyticities in the limiting g.s.e. per particle and unit density of the **homogeneous ideal anyon gas** (Although it has not been rigorously shown, we may expect the thermodynamic limit to be independent of the shape of the domain (and otherwise take the infimum over reasonable shapes).)

$$e(\alpha) := \liminf_{N \rightarrow \infty} E_N(\alpha, D)/N^2. \quad (45)$$

Most details about this function are still open, but from a further analysis of the homogeneous ideal anyon gas on the unit square Q (dividing it into smaller squares), one can at least derive the rigorous uniform bounds (cf. Fig. 7) (Lundholm and Seiringer, 2018)

$$\frac{1}{4} \max\{\tilde{E}_2(\alpha_N), F_2(\alpha_2)\} \leq e(\alpha) \leq 2\pi^2, \quad (46)$$

and

$$\alpha_2 \lesssim e(\alpha) \lesssim \alpha_2, \quad (47)$$

modulo lower and upper universal constants (certainly not optimal). Subject to the assumption that $e(\alpha)$ indeed has a fractal structure that captures universal aspects of planar geometry, a conjecture on its possible form can be given as in Fig. 8; cf. (Lankhorst et al., 2018).

Some states of particular interest

We saw above that there is a nontrivial and delicate balance between exclusion and uncertainty in the ground state energy. Certain types of states have been proposed (Lundholm, 2017; Lundholm and Solovej, 2013b) to minimize the kinetic energy $\hat{T}_{\text{sym} \rightarrow \alpha}$ at particular values of the statistics parameter: in the case of $\alpha = \mu/\nu \in [0, 1]$ being an *even*-numerator reduced fraction, and for $N = \nu K$, $K = 1, 2, \dots$, a suitable sequence of particle numbers, let

Fig. 8 Universal energy phenomena in 2D, from Lankhorst et al. (2018): lowest energy branch of a 100×100 square Josephson junction array (left/blue) resp. the Hofstadter butterfly (right/orange), which also is proportional to the critical temperature of a superconducting square network. (For comparison, $\alpha \sim 2f$)

$$\Psi_\alpha := \prod_{j < k} |z_{jk}|^{-\alpha} \mathcal{S} \left[\prod_{q=1}^v \prod_{(j,k) \in \mathcal{E}_q} (\bar{z}_{jk})^\mu \right] \prod_{l=1}^N \psi_0(\mathbf{x}_l), \quad (48)$$

while for odd numerators μ , let

$$\Psi_\alpha := \prod_{j < k} |z_{jk}|^{-\alpha} \mathcal{S} \left[\prod_{q=1}^v \prod_{(j,k) \in \mathcal{E}_q} (\bar{z}_{jk})^\mu \bigwedge_{k=0}^{K-1} \psi_k(\mathbf{x}_{l \in \mathcal{V}_q}) \right]. \quad (49)$$

Here $z_{jk} := z_j - z_k$ are the pairwise relative complex coordinates and we have grouped, or “colored,” the particles into v different colors where $G_q = (\mathcal{V}_q, \mathcal{E}_q)$ denotes the complete graph over each such group of $|\mathcal{V}_q| = K$ vertices particles (see Fig. 9). The symmetrization $\mathcal{S}$ over all the particles then amounts to symmetrization over all such colorings and can be viewed as passing from a set of distinguishable particles (by color) to indistinguishable (cf., Regnault et al., 2008). The ψ_k , $k = 0, 1, 2, \dots$, are the eigenstates (ordered by increasing energy) of the corresponding one-body Hamiltonian $\hat{H}_1$. The states Ψ_α are moderately singular and so we should actually consider $\Psi = \Phi \Psi_\alpha \in L^2_{\text{sym}}(\mathbb{R}^{2N})$ with Φ a suitably chosen regularization factor to allow inclusion into the domain of $\hat{T}_{\text{sym} \rightarrow \alpha}$.

Some of the reasons why these states appear to be of interest in the many-anyon problem include:

- They have the right average angular momentum (24) and are (for harmonic trap and certain K) homogeneous with a degree suitable to optimize the bound (23).
- They enjoy certain clustering properties that are beneficial to minimize the pair repulsion $V_{\text{stat}}(r)$ on large scales r . States of the form (48) for $\mu = 2$, $v = 3, 5, \dots$ are known in the FQHE context as Read–Rezayi states and are known to form clusters of v particles bound to μ vortices (Cappelli et al., 2001; Read and Rezayi, 1999), while (49) for $\mu = 1$, $v = 2$ correspond to Dyson–Moore–Read/BCS/Pfaffian states subject to pairing (Dyson, 1967; Moore and Read, 1991). Further, excitations on top of these states appear to have non-abelian character (Bonderson et al., 2011; Nayak et al., 2008; Stern, 2008).
- They manifest certain structural stabilities with the smallness of $1 \leq \mu \leq v$, similar to the Laughlin states of the FQHE and indicative of a scale of robustness.
- Some of the states (48) are exact but moderately singular/generalized low-energy eigenfunctions of the Hamiltonian with singular boundary conditions (cf. point interactions below, Section “Point-interacting anyons”) (Chou, 1991; Murthy et al., 1992).

The nonideal anyon gas

The “average(/constant)-field” approach, suggesting (29), leads to difficulties when applied to strictly ideal and pointlike particles, and it is both realistic and helpful to instead consider extended particles as well as other nonideal models of anyon gases that can more easily incorporate the average effects of exchange phases or flux. Heuristic approaches to ensure averaged influence of the statistics include a “self-consistency argument” wherein a typical cyclotron orbit of the generated field ought to contain a large number of particles, suggesting a better approximation if (Chen et al., 1989; Trugenberger, 1992b)

$$\alpha_2 \ll 1 \quad \text{or} \quad (1 - \alpha_2)^2 \ll 1 \quad (50)$$

(i.e., slightly better around fermions due to Pauli repulsion) as well as a similar orbital argument but based instead on the scattering angles of combined Aharonov–Bohm and hard-disk interaction (Caenepeel and MacKenzie, 1994), again suggesting the conditions (50).

Fig. 9 A coloring of $N = 12$ particles with $v = 3$ colors into $K = 4$ 3-clusters V_q^* . Each colored edge $(j, k) \in E_q$ corresponds to one unit $-\mu$ of pairwise angular momentum. Also shown is the contribution to the magnetic potential $\alpha \mathbf{A}_j$ and the current $\mathbf{J}_j$ of particle j due solely to the 3-cluster V_1^* . From Lundholm D (2017) Many-anyon trial states. Physical Review A 96: 012116

The extended anyon gas

In the **extended anyon gas**, we work in the magnetic perspective and replace the point magnetic fluxes of ideal anyons by extended fluxes. For simplicity (and not completely ad hoc from the perspective of emergent models), we may consider the flux to be constantly spread over a disk-shaped magnetic field attached to each particle, with radius $R > 0$. We then replace the anyon magnetic potentials (15) by

$$A_j^R(\mathbf{x}) := \sum_{k \neq j} \frac{(\mathbf{x}_j - \mathbf{x}_k)^\perp}{|\mathbf{x}_j - \mathbf{x}_k|^2}, \quad |\mathbf{x}|_R := \max\{|\mathbf{x}|, R\}, \quad (51)$$

so that, if $\mathbb{1}_{D(\mathbf{y}, R)}$ denotes the indicator function on a disk of radius R centered at $\mathbf{y}$, the field is

$$\text{curl}_{\mathbf{x}_j} \alpha A_j^R = 2\pi\alpha \sum_{k \neq j} \frac{\mathbb{1}_{D(\mathbf{x}_k, R)}(\mathbf{x}_j)}{\pi R^2} \xrightarrow{R \rightarrow 0} 2\pi\alpha \sum_{k \neq j} \delta_{\mathbf{x}_k}(\mathbf{x}_j).$$

The kinetic energy of the extended anyon gas with bosons as reference is then

$$\hat{T}_{\text{sym} \rightarrow \alpha}^R := \frac{\hbar^2}{2m} \sum_{j=1}^N \left(-i\nabla_{\mathbf{x}_j} + \alpha A_j^R \right)^2,$$

acting on L_{sym}^2 while if we use fermions as reference then

$$\hat{T}_{\text{asym} \rightarrow \alpha}^R := \frac{\hbar^2}{2m} \sum_{j=1}^N \left(-i\nabla_{\mathbf{x}_j} + (\alpha - 1)A_j^R \right)^2,$$

acting on L_{asym}^2 .

There is now an additional natural dimensionless parameter in the problem that can be defined as the ratio of the size of the magnetic flux disk to the average interparticle distance,

$$\bar{\gamma} := R\bar{Q}^{-1/2}. \quad (52)$$

This density parameter has been called the **magnetic filling ratio** in Trugenberger (1992a, b) and Larson and Lundholm (2018). The limit $\bar{\gamma} = 0$ corresponds to ideal anyons while $\bar{\gamma} \sim 1$ is the “smearing” limit when particles typically begin to overlap, and $\bar{\gamma} \rightarrow \infty$ would describe the constant-field limit.

At any fixed choice of the two parameters $\alpha \in \mathbb{R}$, $\bar{\gamma} \geq 0$, the energy per particle and unit of density of the **homogeneous extended anyon gas** may thusly be defined via the thermodynamic limit

$$e_{\text{sym/asym}}^{\alpha, R}(\alpha, \bar{\gamma}) := \liminf_{\substack{N, L \rightarrow \infty \\ N/L^2 = \bar{Q}}} \frac{E_N(\alpha, R, LQ)}{\bar{Q}N}, \quad (53)$$

where $E_N(\alpha, R, LQ)$ denotes the g.s. energy of the respective operator $\hat{T}_{\text{sym/asym} \rightarrow \alpha}^R$ on $L_{\text{sym/asym}}^2(LQ^N)$. A corresponding TF-type functional for a **local-density approximation** within a trapping potential V is then

$$\mathcal{E}_{\text{sym/asym}}^{\alpha, R}[\varrho] := \int_{\mathbb{R}^2} \left[e_{\text{sym/asym}}^{\alpha, R}(\alpha, RQ(\mathbf{x})^{1/2}) \varrho(\mathbf{x})^2 + V(\mathbf{x})\varrho(\mathbf{x}) \right] d\mathbf{x}, \quad (54)$$

with $\int_{\mathbb{R}^2} \varrho = N$.

The qualitative analysis of local exclusion effects of the ideal gas discussed in Section “Local exclusion principle and degeneracy pressure for the ideal anyon gas” has been extended to the extended gas, both in the bosonic and the fermionic references. Up to constants, one finds the qualitative bounds (Larson and Lundholm, 2018)

$$e_{\text{sym}}(\alpha, \bar{\gamma}) \gtrsim \begin{cases} |\ln \bar{\gamma}|^{-1} + \alpha_\infty, & \bar{\gamma} \ll 1 \text{ } (\alpha \text{ fixed}), \\ |\alpha|, & \bar{\gamma} \gtrsim 1, \end{cases}$$

where the first regime is a combination of a dilute 2D Bose gas (Lieb and Yngvason, 2001; Schick, 1971) and the strongest of the two lower bounds (46) for the ideal gas at odd numerators, $\tilde{E}_2(\alpha_\infty) \gtrsim \alpha_\infty$, while the second regime indeed captures the constant-field energy (29) for arbitrarily large α . The full regime $\bar{\gamma} \lesssim 1$ is more difficult to describe since it covers both soft-core and hard-core behaviors (see Section “Other interactions and fields”), and we should expect to replace α_∞ with α_2 in a suitable limit. Trugenberger (1992b) suggested that this gas with fixed extension parameter $R > 0$ will at low temperatures prefer to adjust its density to $\bar{\gamma} \gtrsim 1$, where the average field approximation is good and the gas becomes a superfluid, while for high temperatures the density drops, $\bar{\gamma} \ll 1$, the average-field loses validity and superfluidity is lost.

In the fermionic reference (Girardot and Rougerie, 2022)

$$e_{\text{asym}}(\alpha, \bar{\gamma}) \gtrsim \begin{cases} \alpha_2, & \bar{\gamma} \lesssim 1, \\ 1, & \bar{\gamma} \gtrsim 1. \end{cases}$$

In this case the inherent Pauli principle improves the dependence to nearest neighbor due to its scale independence. Note that both energies $e_{\text{sym/asym}}$ must be periodic in α at $\bar{\gamma} = 0$, but not at any finite $\bar{\gamma} > 0$, which therefore requires an interesting interpolation between the regimes.

Almost-bosonic anyons

The average field approach (29) can be made fully rigorous in the limit $N \rightarrow \infty$ close to bosons:

$$\alpha = \beta/N \rightarrow 0, \quad \text{at fixed } \beta \in \mathbb{R},$$

in which the interaction may indeed be treated in a mean-field sense if anyons are also extended/smeared out to a finite size $R > 0$, as above. It is even possible to simultaneously take $R \sim N^{-\eta} \rightarrow 0$ at some sufficiently slow rate η (an “almost-ideal” limit). The idea is then as a final step to take $\beta = \alpha N$ (total flux) large (then “less bosonic”) and study the appropriate ground-state energy functionals in this limit. Because of this particular order of limits, it is not completely clear whether this indeed describes the ideal anyon gas as defined above, or perhaps some nonideal model (see Section “Other interactions and fields”). We shall simply refer to it as “**almost-bosonic**” anyons.

In any case, the first steps above yield the seemingly *correct average-field functional* w.r.t. bosons for any fixed $\beta \in \mathbb{R}$ (Lundholm and Rougerie, 2015):

$$\mathcal{E}_\beta^{\text{af}}[\psi] = \int_{\mathbb{R}^2} \left[|(-i\nabla + \beta \mathbf{A}[|\psi|^2])\psi|^2 + V|\psi|^2 \right]. \quad (55)$$

The magnetic potential $\mathbf{A}[\varrho = |\psi|^2]$ is chosen such that it generates exactly the field $2\pi\varrho$:

$$\text{curl } \beta \mathbf{A}[\varrho](\mathbf{x}) = 2\pi\beta\varrho(\mathbf{x}), \quad \int_{\mathbb{R}^2} \varrho = 1. \quad (56)$$

Thus, the *scalar* self-interaction of the GP model (28) is here replaced with a *magnetic* self-interaction. This produces a peculiar new balancing problem, namely, in order to lower its energy in the self-generated magnetic field, as the coupling β (total number of flux units) grows, there needs to be an increasing phase and angular momentum in $\psi = |\psi|e^{i\phi}$ to cancel this magnetic field: (Due to the reasons described below, the cancellation is not complete, but both terms in (57) contribute an energy of order β .)

$$|(-i\nabla + \beta \mathbf{A})\psi|^2 = |\nabla|\psi||^2 + |\nabla\phi + \beta \mathbf{A}|^2|\psi|^2. \quad (57)$$

Further, in order to preserve regularity, any nontrivial such phase circulation must appear in the form of quantized vortices. On a typical disk $D(\mathbf{x}, R)$, the phase circulation

$$\Phi(\mathbf{x}, R) := \oint_{\partial D(\mathbf{x}, R)} \beta \mathbf{A} \cdot d\mathbf{r} \approx - \int_{D(\mathbf{x}, R)} \text{curl } \nabla\phi \, d\mathbf{y} \quad (58)$$

then needs to minimize the residual angular momentum,

$$\int_0^{2\pi} |\partial_\varphi \phi + \beta A_\varphi|^2 \, d\varphi \geq \min_{q \in \mathbb{Z}} |q - \Phi(\mathbf{x}, R)|^2. \quad (59)$$

However, the amount of flux to be canceled by each vortex also depends on the typical value of the density ϱ there, which therefore sets a varying length scale for vortex formation (Correggi et al., 2017). It is thus expected (see also Chen et al. (1989) for an early conjecture) and indeed confirmed in numerical studies (Correggi et al., 2019; Girardot, 2021) that there is the formation of an Abrikosov-like vortex lattice. However, unlike in the Abrikosov setting with homogeneous rotation/field, the density of vortices here follows the average density profile in the trap V , which for $\beta \gg 1$ turns out to be given again by the minimizer of an effective Thomas–Fermi-type functional (Correggi et al., 2017):

$$\mathcal{E}_\beta^{\text{aTF}}[\varrho] := \int_{\mathbb{R}^2} [C_{\text{aTF}}|\beta|\varrho(\mathbf{x})|^2 + V(\mathbf{x})\varrho(\mathbf{x})] \, d\mathbf{x}. \quad (60)$$

Indeed, numerical simulations (Correggi et al., 2019; Girardot, 2021) (see Fig. 10) confirm the theoretical prediction of Correggi et al. (2017, 2018) that the g.s. ψ_β^{af} of (55) exhibits an approximately triangular vortex lattice distribution with scales set by the TF profile (minimizer) $\varrho_\beta^{\text{aTF}}$ of (60), and it is further estimated numerically that (Correggi et al., 2019)

$$C_{\text{aTF}} \approx 4\pi^{3/2}/3 \approx 1.18 \times 2\pi. \quad (61)$$

The fact that this constant is strictly bigger than the fermionic TF constant and constant-field prediction (Also in comparison to Fig. 5, Chitra and Sen, who estimated a substantially larger factor (Chitra and Sen, 1992), assumed rotational symmetry for the density to simplify their functional, plus added a hard-core delta regularization that itself amounts to the constant-field energy

Fig. 10 Numerical simulation of the ground-state density $|\psi_\beta^{\text{af}}|^2$ in the average-field functional (55) for $\beta = 90$ in a harmonic trap, averaged over rotations and then compared with the exact minimizer $\varrho_\beta^{\text{aTF}}$ of (60). From Correggi M, Duboscq R, Lundholm D, and Rougerie N (2019) Vortex patterns in the almost-bosonic anyon gas. EPL (Europhysics Letters) 126: 20005

$2\pi|\beta|\varrho^2$.) 2π can be understood from the microscopic lattice inhomogeneity of $|\psi_\beta^{\text{af}}|^2$ as compared to its average density $\varrho_\beta^{\text{aTF}}$, which effectively raises the energy by a factor that is at least as big as the Abrikosov constant (≈ 1.1596 ; cf., Aftalion et al., 2006a, b).

Almost-fermionic anyons

A similar regularization approach can be taken close to fermions:

$$\alpha = 1 - \beta/\sqrt{N} \rightarrow 1, \quad \beta, \hbar \text{ fixed},$$

for which the leading terms of the kinetic energy can be compared with the Fermi gas $E_N(\alpha = 1) \sim 2\pi N^2$, $N \rightarrow \infty$. By rescaling the parameters, it is equivalent to study a semiclassical mean-field limit

$$\alpha = 1 - \beta/N \rightarrow 1, \quad \hbar \sim N^{-1/2} \rightarrow 0.$$

Also here we can allow “almost-ideal” or “virtually” extended anyons, $0 < R \sim N^{-\eta} \rightarrow 0$, if the rate η is small enough (The rate is better than for bosons because of the Pauli principle; cf. (50)).

This **almost-fermionic** approach takes us back to the actual TF functional for fermions (27), which remains correct for any finite β in this limit (Girardot, 2021; Girardot and Rougerie, 2021). More precisely, one obtains a semiclassical **Vlasov functional**:

$$\mathcal{E}_\beta^{\text{Vla}}[\mu] := \frac{1}{(2\pi)^2} \int_{\mathbb{R}^4} |\mathbf{p} + \beta \mathbf{A}[\varrho]|^2 \mu(\mathbf{x}, \mathbf{p}) \, d\mathbf{x} d\mathbf{p} + \int_{\mathbb{R}^2} V \varrho \, d\mathbf{x}$$

for $0 \leq \mu(\mathbf{x}, \mathbf{p}) \leq 1$ a measure on phase space $\mathbb{R}^4$, which is subject to the Pauli principle and normalized $\int_{\mathbb{R}^4} \mu = (2\pi)^2$. The minimizing measure μ of this functional is the corresponding filled Fermi sea:

$$\mu(\mathbf{x}, \mathbf{p}) = \mathbb{1}_{\{|\mathbf{p} + \beta \mathbf{A}[\varrho](\mathbf{x})|^2 \leq 4\pi\varrho(\mathbf{x})\}}, \quad (62)$$

with **spatial density** $\varrho = \varrho^{\text{TF}}$ independent of β :

$$\varrho(\mathbf{x}) = \frac{1}{(2\pi)^2} \int_{\mathbb{R}^2} \mu(\mathbf{x}, \mathbf{p}) \, d\mathbf{p} = (4\pi)^{-1} (\lambda^{\text{TF}} - V(\mathbf{x}))_+.$$

The momentum density $t = t_\beta^{\text{TF}}$,

$$t(\mathbf{p}) = \frac{1}{(2\pi)^2} \int_{\mathbb{R}^2} \mu(\mathbf{x}, \mathbf{p}) d\mathbf{x},$$

does depend on β , however, in a nonlocal way. The energy $\mathcal{E}_\beta^{\text{Vla}}[\mu] = \mathcal{E}^{\text{TF}}[\varrho^{\text{TF}}]$ is locally a constant at $\alpha \approx 1$ in this approximation, thus confirming this aspect of Fig. 5.

The almost-fermionic regime was also studied numerically by Girardot (2021) using a Hartree–Fock approach, that is, on Slater determinants, and with a self-generated field $B = 2\pi\beta\varrho/N$ (total flux $2\pi\beta$), showing good agreements to the above. In fact, it can be interpreted as a multicomponent version of the bosonic functional (55) on orthogonal states ψ_k , $k = 1, 2, \dots, N$. These are then able to complement each other's densities so as to fill in any holes left by vortices, and thus eventually smoothen out the overall density profile:

$$\varrho(\mathbf{x}) = \sum_{k=1}^N |\psi_k(\mathbf{x})|^2 \approx \varrho^{\text{TF}}(\mathbf{x}), \quad (63)$$

thereby validating the “constant-field” (local density) approximation in this regime when β is not too large.

Magnetic TF theory

For higher ratios of the magnetic field to the density one may expect (Girardot, 2021) a magnetic Thomas–Fermi theory (Lieb et al., 1995; McEuen et al., 1992) to become valid. Namely, for a field $B(\mathbf{x})$, which is approximately constant on the scale of the trapping potential V , we can think of distributing the density

$$\varrho(\mathbf{x}) = \sum_{n=0}^{\infty} \varrho_n(\mathbf{x})$$

locally into the Landau levels (LLs) $\mathcal{H}_n$ of the corresponding one-body Landau Hamiltonian (In our units the cyclotron frequency is $\omega_c = 2|B|$.)

$$H_1^{\text{Lan}} = (-i\nabla_{\mathbf{x}} + B\mathbf{x}^\perp/2)^2 = \sum_{n=0}^{\infty} |B|(2n+1)\mathbb{1}_{\mathcal{H}_n}. \quad (64)$$

The degeneracy (per unit area) of each level is the number of flux units (per unit area), $d_B := |B|/(2\pi)$. Thus, defining the corresponding expected local magnetic energy at a given density ϱ ,

$$j_B(\varrho) := \sum_{n=0}^{\infty} |B|(2n+1)\varrho_n, \quad 0 \leq \varrho_n \leq d_B,$$

the magnetic TF functional for N fermions in a fixed external field $B > 0$ is then

$$\mathcal{E}^{\text{mTF}}[\varrho] := \int_{\mathbb{R}^2} [j_B(\varrho(\mathbf{x})) + V(\mathbf{x})\varrho(\mathbf{x})] d\mathbf{x}, \quad \int_{\mathbb{R}^2} \varrho = N. \quad (65)$$

At fixed B and ϱ , in order to minimize $j_B(\varrho)$ we fill all $N_B := \lfloor \varrho/d_B \rfloor$ lower Landau levels maximally:

$$\varrho_n = \begin{cases} d_B, & 0 \leq n \leq N_B - 1, \\ \varrho - N_B d_B, & n = N_B, \\ 0, & n \geq N_B + 1, \end{cases}$$

so that in the limit $B \rightarrow 0$, implying $d_B \rightarrow 0$,

$$j_B(\varrho) \approx \sum_{n=0}^{N_B-1} |B|(2n+1)d_B = |B|N_B^2 d_B \approx |B|\varrho^2/d_B = 2\pi\varrho^2,$$

returning us to the usual TF for the free Fermi gas. On the other hand, if B is large enough that $d_B \geq \varrho$, then all particles will fit into the lowest Landau level (LLL):

$$j_B(\varrho) = |B|\varrho. \quad (66)$$

Now, considering a sufficiently extended anyon gas and formally taking the anyonic (average) magnetic field $B(\mathbf{x}) = 2\pi\beta\varrho(\mathbf{x})$, where $\beta = 1 - \alpha \in [0, 1]$ is the number of flux units per particle attached to fermions, we then obtain a magnetic TF self-interaction functional for anyons:

$$\mathcal{E}_\beta^{\text{amTF}}[\varrho] := \int_{\mathbb{R}^2} \left[j_{B=2\pi\beta\varrho(\mathbf{x})}(\varrho(\mathbf{x})) + V(\mathbf{x})\varrho(\mathbf{x}) \right] d\mathbf{x}. \quad (67)$$

At any point $\mathbf{x} \in \mathbb{R}^2$ where $\varrho(\mathbf{x}) \neq 0$, let us consider there the fractions of density $f_n := \varrho_n(\mathbf{x})/\varrho(\mathbf{x})$ in the LLs:

$$\frac{j_B(\varrho)}{2\pi\varrho^2} = \sum_{n=0}^{\infty} \beta(2n+1)f_n, \quad 0 \leq f_n \leq \beta \leq 1,$$

which again is minimized by filling the lowest $N_B = \lfloor \beta^{-1} \rfloor$ levels:

$$f_n = \begin{cases} \beta, & 0 \leq n \leq \lfloor \beta^{-1} \rfloor - 1, \\ 1 - \beta \lfloor \beta^{-1} \rfloor, & n = \lfloor \beta^{-1} \rfloor, \\ 0, & n \geq \lfloor \beta^{-1} \rfloor + 1. \end{cases}$$

Hence, our minimum is

$$\frac{j_B(\varrho)}{2\pi\varrho^2} = \sum_{n=0}^{\lfloor \beta^{-1} \rfloor - 1} (2n+1)\beta^2 + \beta(2\lfloor \beta^{-1} \rfloor + 1)(1 - \beta \lfloor \beta^{-1} \rfloor),$$

which simplifies to

$$\frac{j_B(\varrho)}{2\pi\varrho^2} - 1 = \beta^2(1 - \{\beta^{-1}\})\{\beta^{-1}\} =: M(\beta) \in [0, \beta^2/4],$$

where $\{\beta^{-1}\} = \beta^{-1} - \lfloor \beta^{-1} \rfloor \in [0, 1)$ is the fractional part of β^{-1} . Therefore our proposed functional for the g.s. (a pointwise lower bound to (67)) takes the form

$$\tilde{\mathcal{E}}_\beta^{\text{amTF}}[\varrho] := \int_{\mathbb{R}^2} [2\pi\varrho(\mathbf{x})^2(1 + M(\beta)) + V(\mathbf{x})\varrho(\mathbf{x})] d\mathbf{x}, \quad (68)$$

thus refining both the “constant-field” approximation (29) around fermions and the above almost-fermionic approximation.

The corresponding energy landscape (see Fig. 11) is now indicative of **stability** at the Fermi point $\beta = 0$. A possible interpretation for the gas is that the discretization of the Fermi sea into Landau levels imposes a more rigid structure in phase space, that is, as the attached flux β per particle increases, particles come from plane-wave states, which homogenize easily in space and then need to start organizing into the respective cyclotron orbits with decreasing radii as the field increases. Thus the Fermi sea becomes less fluid and more crystalline, with the most synergetic situation when a whole number of levels are approximately filled ($\{\beta^{-1}\} \approx 0$ or 1) so adjustments to the density can be accommodated at all levels in parallel while keeping the fractions f_n constant, and least synergetic when half a level is filled ($\{\beta^{-1}\} \approx 1/2$) and a larger fraction $\beta\{\beta^{-1}\}$ of particles need to organize their motion into that specific LL. However, we cannot expect this picture to be valid all the way to bosons at $\beta = 1$ (compare also (50)) because there will also be correlations across Landau levels, leading to effective attractions, clustering, and condensation, and for example, if the LLL is filled and there are only few particles in the first-excited LL, then one might consider the statistics transmutation situation discussed below where the excited particles would effectively rather be treated as bosons than fermions.

An analysis at these seemingly beneficial fractions $\alpha = 1 - 1/n$ was conducted by [Chen et al. \(1989\)](#) in the homogeneous setting (building on ([Fetter et al., 1989](#))), where they indeed observed characteristics of **superfluidity**. For example, the energy there increases linearly when a small external magnetic field is applied in either direction, which is interpreted as a Meissner effect.

Fig. 11 The factor $M(\beta) = \beta^2(1 - \{\beta^{-1}\})\{\beta^{-1}\} \leq \beta^2/4$ (r.h.s. *dashed*) in the magnetic TF functional (68) as a function of the relative statistics parameter $\beta = 1 - \alpha$ around fermions $\beta = 0$.

Recently another approach to a DFT for anyons, via Kohn–Sham theory with neglected exchange correlation (then similar to self-consistent Hartree–Fock) was taken by Hu et al. to study these effects (Hu et al., 2021). Their numerics agree well with the semiclassical TF approximation close to fermions and show significant deviations only when the magnetic field is strong enough that particles in the bulk occupy only the lowest few LLs. For trapped systems they also observe a boundary effect, which can compensate for the otherwise necessary fractional filling of LLs, but which vanishes in the thermodynamic limit. Indeed, due to the many parallels to the FQHE, Chen et al. suggested that “the physics of the anyon gas at general values of θ is likely to be quite rich and to depend quite strongly on ‘number-theoretic’ properties of θ .”

Point-interacting anyons

Introducing **point or contact interactions** corresponds to specifying the behavior of wave functions at the diagonal (contact) set $\triangle_N$, that is, imposing boundary conditions there so as to render the Hamiltonian self-adjoint while allowing a different behavior than that of the canonical/free choice (Friedrichs; cf. Section “Kinetic energy”). This is equivalent to considering *all* of the possible boundary conditions, or **self-adjoint extensions**, of the operator $\hat{T}_\alpha$ starting from its initial definition on wave functions vanishing at $\triangle_N$ and having finite expected energy in the standard sense (11). For general N , this is difficult even for distinguishable particles, but one may reduce this problem significantly by adding assumptions such as translation and scale covariance. Our present understanding of general point-interacting (and pointlike, that is, nonextended) anyons is currently rather limited (cf., Dell’Antonio et al., 1997), however for $N = 2$ anyons, the situation is now well understood (Bourdeau and Sorkin, 1992; Correggi and Oddis, 2018; Coutinho et al., 1992; Grundberg et al., 1991; Manuel and Tarrach, 1991; Murthy et al., 1992; Oddis, 2020) and extends the corresponding analysis of the standard nonmagnetic two-body point-interaction problem in various dimensions (see, e.g., Albeverio et al., 2005).

For $\alpha_2 \neq 1$ (nonfermions), the problem admits a circle of different possibilities for point interaction, all of which are attractive and correspond to allowing wave functions with singularities at the diagonals. One simple way to understand this is via the form (12), which in the s-wave (radially symmetric) with $\Psi = r^{\pm\alpha_2} \phi(r)$ turns out to be equivalent to (Manuel and Tarrach, 1991; Oddis, 2020)

$$\int_0^\infty |\phi'(r)|^2 r^{d_\alpha-1} dr, \quad (69)$$

for a parameter giving an effective “intermediate dimension”

$$2 \leq d_\alpha := 2 + 2\alpha_2 \leq 4. \quad (70)$$

Thus, for bosons the problem is indeed two-dimensional and has a circle of extensions, where a unique one $\hat{T}_{\text{sym}}$ (Friedrichs, $\Psi \sim 1$ as $r \rightarrow 0$) is nonnegative. For fermions, it is more akin to four dimensions where the corresponding bosonic problem is essentially self-adjoint, that is, has a unique extension $\hat{T}_{\text{asym}}$ (Friedrichs, $\Psi \sim r$). For proper anyons the situation is intermediate and actually closest akin to three dimensions. In this case there is again a circle of extensions, but the circle now splits into two halves (cf. Fig. 2): in one half one has negative extensions and a scale of increasingly negative bound states, and in the other, a scale of decreasingly-nonnegative (i.e., increasingly attractive) extensions. The largest (least attractive/“free”) such extension is the usual free kinetic energy $\hat{T}_\alpha = \hat{T}_\alpha^{\text{F}}$ (Friedrichs, $\Psi \sim r^{\alpha_2}$) while the smallest $\hat{T}_\alpha^{\text{K}}$ (most attractive, $\Psi \sim r^{-\alpha_2}$, and known as the **Krein extension** (Alonso and Simon, 1980)) is also singled out as scale covariant while all the other intermediate extensions have scale.

If these observations extend to $N \geq 3$ particles, then it is reasonable to expect such “**kreinyons**” to be of interest in physics, and in fact may even correspond to some of the moderately singular “noninterpolating” exact eigenstates (Murthy et al., 1992) found in the harmonic oscillator problem (cf. Section “Some states of particular interest”). Other relevant connections of anyons to geometry and quantum mechanics on cone-like manifolds were reviewed in Jackiw (1990).

Other interactions and fields

One can obviously also include other (scalar) interactions into the magnetic models for anyons, as well as an external magnetic field (coupled by a charge $-q$), for example

$$\hat{H}_{N\neq} = \frac{\hbar^2}{2m} \sum_{j=1}^N \left(-i\nabla_{\mathbf{x}_j} + q\mathbf{A}_{\text{ext}} + \alpha\mathbf{A}_j^R \right)^2 + \sum_{j=1}^N V(\mathbf{x}_j) + \sum_{j < k} W(\mathbf{x}_j - \mathbf{x}_k). \quad (71)$$

Reasonable external fields have been incorporated into some parts of the average-field theory (Girardot, 2020; Girardot and Rougerie, 2021), as well as point interactions (Correggi and Fermi, 2021; Oddis, 2020), and interacting anyons are certainly relevant in emergent models, as we will see below. Coulomb interactions and the thermodynamic stability of “anyonic matter” were addressed in Lundholm and Solovej (2014), Lundholm and Seiringer (2018), and Lundholm (2019). We note that since scalar interactions can show features akin to statistics, such as effective TF-type functionals and degeneracy pressure (Larson et al., 2021; Lieb et al., 2005; Lundholm, 2019; Lundholm et al., 2015, 2016), it is important to isolate the features that are due to the actual quantum statistics (cf., Lambert et al. (2022)).

Another way to view the effect of the magnetic flux disks in the average-field approximation is as an effective scalar potential

$$W(\mathbf{x}_j - \mathbf{x}_k) = \frac{2\pi|\alpha|}{\pi R^2} \mathbb{1}_{D(\mathbf{x}_k, R)}(\mathbf{x}_j) \quad (72)$$

added to anyons (in the bosonic reference, this is indeed correct as a lower bound [Larson and Lundholm, 2018](#)). One may then consider the combination of parameters

$$\frac{|\alpha|}{\bar{\rho} R^2} = |\alpha| \bar{\gamma}^{-2}, \quad (73)$$

that is, the height of the potential compared to the average density, as a dimensionless measure of interaction strength, and for fixed α and $\bar{\gamma} \ll 1$, this then corresponds to a hard-core interaction, while if $|\alpha| \bar{\gamma}^{-2} \ll 1$, such as if $\sqrt{|\alpha|} \ll \bar{\gamma}$ where either side may be taken to grow or decline, then W instead corresponds to a weak soft-core interaction. With the convergence rates η currently allowed in the derivations of almost-bosonic and almost-fermionic models ($0 < \eta < 1/4$ ([Girardot, 2020](#)) resp. $0 < \eta < 1/3$ ([Girardot and Rougerie, 2022](#))), we find that on a fixed homogeneous trap, $\bar{\gamma} \sim N^{1/2-\eta} \rightarrow \infty$ and $|\alpha| \bar{\gamma}^{-2} \sim N^{2\eta-2} \rightarrow 0$ resp. $|1 - \alpha| \bar{\gamma}^{-2} \sim N^{2\eta-3/2} \rightarrow 0$ as $N \rightarrow \infty$, that is a combined high-density and weak soft-core limit, indeed beneficial to the average-field approximation.

Lowest Landau level (LLL) anyons

If the anyons are ideal but in a strong external constant magnetic field, then all anyons fall into the LLL (cf. (66)), and the model actually becomes exactly solvable. The reason is that their wave function becomes (anti)analytic (modulo a Gaussian factor) and corresponds to changing the Jastrow factors in (48) and (49) from $|z_{jk}|^{-\alpha}$ to $(\bar{z}_{jk})^\alpha$, $\alpha \in [0, 1]$. It results in a description in terms of **fractional exclusion statistics** (cf., [Haldane, 1991](#)) with one-body occupation numbers (angular momenta) shifted by α , and a relation to Calogero–Sutherland models. We refer to [Ouvry \(2007\)](#) for an overview of this approach.

The non-abelian anyon gas

Let us now generalize our context further and consider an ideal N -**anyon wave function** as *locally* a map (Again, one way to concretize this is to regard the multivalued function Ψ as a ρ -equivariant function on the covering space of $\mathcal{C}^N$, or as a section of a vector bundle $E \rightarrow \mathcal{C}^N$ with fiber $\mathcal{F}$ ([Lundholm and Qvarfordt, 2020](#))).

$$\Psi : \mathcal{C}^N \rightarrow \mathcal{F}, \quad \text{subject to} \quad \Psi(\sigma.X) = \rho(\sigma)\Psi(X), \quad (74)$$

where the **fiber** $\mathcal{F}$ is a Hilbert space of “internal” (nonspatial) degrees of freedom on which B_N acts unitarily (We can even let go of the unitarity condition on reps if one is willing to consider multivalued probability distributions (cf., [Abramsky and Brandenburger, 2011](#))).

$$\rho : B_N \rightarrow \mathbf{U}(\mathcal{F}).$$

Now $\rho(\sigma)$ is an **exchange operator** on $\mathcal{F}$ corresponding to the braid $\sigma \in B_N$. There may be other observables of the considered system acting in $\mathcal{F}$, but for simplicity we here assume that it is finite dimensional, that is, $\mathcal{F} = \mathbb{C}^D$ for some $D \in \mathbb{N}$, and $\mathbf{U}(\mathbb{C}^D) = \mathbf{U}(D)$ is the group of $D \times D$ unitary matrices. We then identify three possibilities for these representations (“reps”):

1. **Irreducible abelian:** $\mathcal{F} = \mathbb{C}$, which is the case we treated above, with elementary exchange phase

$$\rho(\sigma_j) = e^{i\alpha\pi} \quad \text{for all } j,$$

for a fixed statistics parameter α of abelian anyons.

2. **Reducible abelian:** $\mathcal{F} = \mathbb{C}^D$, $D > 1$, where all elementary exchange operators $\rho(\sigma_j)$ commute and thus are simultaneously diagonalizable (We write $A \cong B$ if two matrices or operators are similar, that is, unitarily equivalent.):

$$\rho(\sigma_j) \cong \text{diag}(e^{i\alpha(1)\pi}, \dots, e^{i\alpha(D)\pi}) \quad \text{for all } j,$$

for statistics parameters $\alpha(k)$ corresponding to different sectors of particles that do not interact quantum statistically.

3. **Non-abelian:** $\mathcal{F} = \mathbb{C}^D$, $D > 1$, where not all elementary exchange operators commute:

$$\rho(\sigma_j)\rho(\sigma_k) \neq \rho(\sigma_k)\rho(\sigma_j) \quad \text{for some } j \neq k.$$

Actually, it turns out that

$$D \geq N - 2 \quad \text{if } N \geq 7, \quad (75)$$

because otherwise the rep is necessarily abelian (this is a theorem in the rep theory of the braid group (Formanek, 1996); cf. (Weinberger, 2015), (Lundholm and Qvarfordt, 2020, Theorem 3.13)). Furthermore, if $N \geq 7$ and $D = N - 2$ or $D = N - 1$ then the rep is either abelian or, up to an abelian factor, the non-abelian (reduced) Burau representation. For any other reps, we need $D \geq N$. Because of this last remark, we cannot simply fix the fiber Hilbert space $\mathcal{F}$ or the rank of the representation $D = \dim \mathcal{F}$ and then study growing numbers N of anyons because they will then eventually abelianize. Further, in the non-abelian case it is, as far as this author is aware, not certain whether statistics transmutation is available, that is, whether one may always pass from the geometric to the magnetic perspective (this is a question in topology; see Lundholm and Qvarfordt (2020) and Maciazek and Sawicki (2019) for further discussion). Some models have magnetic formulations however (Kohn, 1987; Lee and Oh, 1994; Wen, 1991), but for simplicity in this overview we will remain in the geometric perspective and furthermore pull in a small sample of results from the **algebraic perspective** as well, where certain reps can be systematically and consistently constructed from elementary **fusion and braiding** rules, and exchange operators can be computed explicitly. The topic is quite complex and extends far outside the scope of this overview; instead we refer to Beer et al. (2018), Lundholm and Qvarfordt (2020), Stern (2008), Nayak et al. (2008), Lahtinen and Pachos (2017), and Masaki et al. (2023) for more detail on the algebraic and diagrammatic aspects of anyon models (and note that the representation theory of the braid group is a still incomplete and very active field of mathematics). Anyons with non-abelian braid group representations are generally called “**non-abelions**” or “**plektons**.”

A **many-anyon model** is a sequence of fiber Hilbert spaces $\mathcal{F}_N$, $D_N = \dim \mathcal{F}_N$, and braid group representations

$$\rho_N : B_N \rightarrow \mathbf{U}(\mathcal{F}_N), \quad N = 1, 2, 3, \dots, \quad (76)$$

together with a sequence of kinetic energy operators

$$\hat{T}_{\rho_N} = \frac{\hbar^2}{2m} \sum_{j=1}^N \left(-i \nabla_{\mathbf{x}_j}^{(\rho_N)} \right)^2 \quad (77)$$

which implement these reps (by means of parallel transport) as the corresponding exchange operators in (74) (One might also require a compatibility between reps ρ_N w.r.t. the embedding sequence $B_{N-1} \hookrightarrow B_N$ of braid groups, which may be nontrivial (see Delaney et al., 2016; Rowell and Wang, 2012)).

The free kinetic energy operator $\hat{T}_{\rho_N}$ is again locally the same as the free Laplacian $\hat{T}_{\text{dist}}$, supplemented with holonomies $\rho_N(\sigma) \in \mathbf{U}(D_N)$ w.r.t. any nontrivial exchange loops $\sigma \in B_N$. Instead of the abelian pair-exchange conditions (7), one now has

$$\Psi(\mathbf{x}_1, \dots, \mathbf{x}_{k'}, \dots, \mathbf{x}_j, \dots, \mathbf{x}_N) = U_{N,p} \Psi(\mathbf{x}_1, \dots, \mathbf{x}_j, \dots, \mathbf{x}_{k'}, \dots, \mathbf{x}_N), \quad (78)$$

with **pair-exchange operators** (Defined up to similarity; note, for example, that $\rho(\sigma_j) \cong \rho(\sigma_k)$ with similarities depending on j and k (Lundholm and Qvarfordt, 2020)).

$$U_{N,p} \cong \rho_N(\sigma_1 \sigma_2 \dots \sigma_p \sigma_{p+1} \sigma_p \dots \sigma_2 \sigma_1) \quad (79)$$

for any counterclockwise two-particle exchange loop in which $p \leq N - 2$ other particles are enclosed, corresponding to the second figure in Fig. 3. We denote their eigenvalues by

$$\text{spec } U_{N,p} = \{e^{i\pi\gamma_k}\}_{k=1,2,\dots,D_N},$$

where we normalize the full range of **statistics parameters** $\gamma_k = \gamma_k(N, p)$ in the interval $(-1, 1]$.

Non-abelions are still harder to treat as perturbations close to bosons or fermions since typically the eigenvalues of $U_{N,p}$ are separated from (or coincide with) ± 1 . Also, because of a lack of general magnetic formulations, it is even more unclear what we should mean with an extended gas of non-abelions, except as derived from emergent models and Berry connections (see below). However, concerning the qualitative features and local exclusion properties for the ideal gas, somewhat analogous results as for the abelian gas may be obtained (Lundholm and Qvarfordt, 2020), as follows:

The N -fractionality is now replaced by

$$\alpha_{N,n} := \min_{p=0,1,\dots,n-2} \beta_{N,p}, \quad n \leq N, \quad (80)$$

where the **pair-exchange parameter** with $p \leq N - 2$ particles enclosed,

$$\beta_{N,p} := \min_{k=1,2,\dots,D_N} |\gamma_k(N, p)| = \text{dist}(\text{spec}(U_{N,p}), +1),$$

is again the arcwise distance (in units of π) from the spectrum of $U_{N,p}$ to $+1$. Then, the statistical repulsion as given both by the Hardy inequality (34) (and its variants, depending on $\alpha_{N,n}$), the local exclusion principle (40) and (41), as well as the degeneracy pressure (43), generalize to the ideal non-abelion gas:

$$\langle \hat{T}_{\rho_N} \rangle_\Psi \gtrsim \alpha_{N,2} \int_{\mathbb{R}^2} \varrho_\Psi(\mathbf{x})^2 d\mathbf{x}. \quad (81)$$

Thus, it is again the nearest-neighbor pair exchange (in the rep ρ_N) that sets the main behavior of the gas w.r.t. fractional exclusion statistics.

Three classes of representations of special interest were considered in some detail in [Lundholm and Qvarfordt \(2020\)](#): Burau, Ising, and Fibonacci. Note that variations of these may arise by composing with abelian models. Some important features have been obtained also for other reps, such as scattering and dilute thermodynamics based on the nearest-neighbor pair exchange ([Mancarella et al., 2013a, b](#); [Verlinde, 1991](#); [Wilczek and Wu, 1990](#)).

Burau

The Burau rep ([Burau, 1935](#)) is a simple deformation of the defining rep of the permutation group, $S_N \rightarrow U(N)$, that also must be reduced ($D_N = N - 1$ or $N - 2$) and unitarized to fit in the above framework. We are only aware of the simplest case $N = 3$, $\mathcal{F} = \mathbb{C}^2$ having been worked out explicitly so far ([Weinberger, 2015](#)), and then

$$\text{spec } U_{3,0} = \{1, -w^2\}, \quad \text{spec } U_{3,1} = \{w^3, -w^3\}$$

for a parameter $w = e^{i\alpha}$, $|\alpha| < 1/3$, of the representation. Here we find $\alpha_{3,2}(w) = 0$ for all such w and indeed there are states that do not vanish on the diagonal because of a lack of exclusion there ([Lundholm and Qvarfordt, 2020](#)).

Ising

Here $D_N = \dim \mathcal{F}_N$ grows roughly as $(\sqrt{2})^N$, which is related to reps of Clifford algebras ([Nayak and Wilczek, 1996](#)) (and there are distinctions between even/odd numbers of such anyons and of fermions which also appear in the models). The spectra of all pair-exchange operators have been computed ([Lundholm and Qvarfordt, 2020](#)):

$$\text{spec } U_{N,p} = \begin{cases} \{e^{-i\pi/8}, e^{i\pi/8}\}, & \text{if } p = 0, \\ \{e^{-i\pi/8}, e^{i\pi/8}\}, & \text{if } p \geq 1 \text{ is odd,} \\ \{e^{-i\pi/8}, e^{i\pi/8}, e^{i\pi/8}, e^{i\pi/8}\}, & \text{if } p \geq 2 \text{ is even,} \end{cases}$$

(in one rep, and their complex conjugates in another rep, and with multiplicities that grow with N). Thus,

$$\alpha_{N,n} = \beta_{N,0} = 1/8 \quad \text{for all } N, n \geq 2,$$

so the Ising gas has an exclusion at the diagonals and a degeneracy pressure. Since these n -fractionalities are independent of n (and N), we do not see any benefits of clustering to minimize statistical repulsion, at this level of inquiry.

Fibonacci

Here $D_N = \dim \mathcal{F}_N$ grows with the Fibonacci sequence so that $D_{N+1}/D_N \xrightarrow{N \rightarrow \infty} \phi$, the golden ratio. Furthermore, the spectra of all pair-exchange operators have been computed ([Qvarfordt, 2017](#)):

$$\text{spec } U_{N,p} = \begin{cases} \{e^{-i\pi/5}, e^{i\pi/5}\}, & \text{if } p = 0, \\ \{e^{-i\pi/5}, e^{i\pi/5}, e^{i\pi/5}\}, & \text{if } p = 1, \\ \{e^{-i\pi/5}, e^{i\pi/5}, e^{i\pi/5}, e^{i\pi/5}\}, & \text{if } p \geq 2, \end{cases}$$

(in one rep, and their complex conjugates in another rep, and with multiplicities that grow with N , also along the Fibonacci sequence). Thus,

$$\alpha_{N,n} = \begin{cases} \beta_{N,0} = 3/5, & \text{if } n = 2, \\ \beta_{N,1} = 1/5, & \text{if } n \geq 3, \end{cases}$$

and therefore also the Fibonacci gas is subject to exclusion at the diagonals and a degeneracy pressure. Since $\alpha_{N,n} < \alpha_{N,2}$ for $n \geq 3$, this may be indicative of clustering in this gas in order to minimize statistical repulsion over long ranges.

Emergence of the anyon gas

In the study of emergent quantum statistics, we typically consider two distinct species of particle, one of which is numerous and numbered by, for example, $N \gg 1$, which we shall refer to as the **bath**, and another species, which is much less numerous, $1 \leq n \ll N$, which we refer to as **tracers** or **impurities**. These two species could be physically the same type of particle but effectively distinguished by some quantum number, such as their Landau level index for example. The bath forms a background and a collective coherence for the tracers so that its macroscopically well-defined state provides a limiting reference frame with respect to which tracers may transmute their properties.

The quantum Hall setting

In the quantum Hall (QH) setting, we assume that all particles are confined to a plane and subject to a large and approximately constant magnetic field $\mathbf{B} = -b\mathbf{e}_z$, $b > 0$, that is, the relevant one-body operator is again the Landau Hamiltonian (64)

$$H_1^{\text{Lan}} = \frac{1}{2m} (-i\hbar\nabla_{\mathbf{x}} + qb\mathbf{x}^\perp/2)^2 = \hbar\omega_c(\hat{a}^\dagger\hat{a} + 1/2),$$

$\omega_c = |qb|/m$, and particles then distribute into the Landau levels (LLs) of this field. The lowest Landau level (LLL) is the kernel of $\hat{a}$ (let us now fix $\hbar = 1$ and $q = -1$):

$$\text{LLL} = \mathcal{H}_0 = \left\{ \psi \in L^2(\mathbb{R}^2) : \psi(\mathbf{x}) = f(z)e^{-\frac{b}{4}|z|^2}, f \text{ analytic} \right\} \quad (82)$$

and spanned by the orthonormal basis of Fock–Darwin states

$$\psi_l(z) = c_l z^l e^{-\frac{b}{4}|z|^2}, \quad l = 0, 1, 2, \dots,$$

for normalization constants $c_l > 0$. We assume electron spin is out of the picture due to the strong band separation, and also that there is a radial trapping potential centered at $z = 0$, penalizing higher angular momenta l .

The first concrete prediction of emergent anyonic statistics was made in the context of the *fractional* quantum Hall effect (FQHE) for electrons (Tsui et al., 1982), that is, fractional filling of the LLL, for which Laughlin proposed the following trial states in the electrons' coordinates $z_j \in \mathbb{C}$, $z = (z_j)_{j=1,\dots,N}$, to explain the effect (Laughlin, 1983, 1999) (Note that these also coincide with the anyonic trial states (48) and (49) if extended to $\alpha = \mu$ with trivial Jastrow factors (Lundholm, 2017).):

$$\Psi_\mu^{\text{Lau}}(z) \propto \prod_{j < k} z_{jk}^\mu e^{-\frac{b}{4}|z|^2}.$$

For electrons, μ is an odd integer so that $\Psi_\mu^{\text{Lau}} \in L^2_{\text{asym}}$. In the case that $\mu = 1$, suitable for an *integer* QH effect, the state corresponds to a Fermi sea filling of LLL with the least angular momentum: $\Psi_{\mu=1}^{\text{Lau}}(z)$ is proportional to

$$\bigwedge_{l=0}^{N-1} \psi_l(z) \propto \det \begin{bmatrix} 1 & 1 & \dots & 1 \\ z_1 & z_2 & \dots & z_N \\ \vdots & \vdots & & \vdots \\ z_1^{N-1} & z_2^{N-1} & \dots & z_N^{N-1} \end{bmatrix} e^{-\frac{b}{4}|z|^2},$$

by Vandermonde's formula for the determinant. For fractional filling $1/\mu$, and to reduce Coulomb interaction energy among electrons, Laughlin thus proposed taking the determinant above to a power $\mu > 1$. On top of such states, Laughlin also considered states of quasiholes pinned to positions $w_k \in \mathbb{C}$, $\mathbf{w} = (w_k)_{k=1,\dots,n}$:

$$\Psi_\mu^{\text{qh}}(\mathbf{w}; z) \propto \prod_{k=1}^n \prod_{j=1}^N (w_k - z_j) \Psi_\mu^{\text{Lau}}(z)$$

(all states with appropriate normalization, and $y_k \leftrightarrow w_k$, $\mathbf{x}_j \leftrightarrow z_j$ respective real and complex coordinates).

Berry phases

Halperin (1984) suggested that if the quasiholes are treated as quantum particles, then they ought to have fractional anyonic statistics, and Arovas, Schrieffer and Wilczek (Arovas et al., 1984) subsequently proposed a **Berry-phase approach** to determine their statistics. Namely, if we view Ψ_μ^{qh} as a map

$$\mathbb{C}^n \rightarrow L^2_{\text{asym}}(\mathbb{R}^{2N}), \quad \mathbf{w} \mapsto \Psi_\mu^{\text{qh}}(\mathbf{w}; \cdot)$$

from the parameters $\mathbf{w}$ into the (fiber) Hilbert space of electrons, then Berry associates to such a geometry a canonical connection (Berry, 1984; Simon, 1983):

$$\tilde{\mathbf{A}}_j(\mathbf{y}) := \langle -i\nabla_{\mathbf{y}_j} \rangle_{\Psi_\mu^{\text{qh}}(\mathbf{y}; \cdot)} = -i \int_{\mathbb{C}^N} \overline{\Psi_\mu^{\text{qh}}(\mathbf{y}; z)} \nabla_{\mathbf{y}_j} \Psi_\mu^{\text{qh}}(\mathbf{y}; z) dz. \quad (83)$$

The holonomies of the connection w.r.t. loops on the parameters, $\sigma : [0, 1] \rightarrow \mathbb{C}^n$,

$$\rho(\sigma) = e^{i\Phi_\sigma}, \quad \Phi_\sigma = \oint_\sigma \sum_{j=1}^n \tilde{\mathbf{A}}_j \cdot d\mathbf{y}_j, \quad (84)$$

are then interpreted to be the exchange phases (1) (now including an “external” field of constant curvature) effectively associated to the motion of the quasiholes in the bath of electrons. Thus, under the **adiabatic assumption** that the electrons move much faster than the holes, one can take statistical averages over $z \in \mathbb{C}^N$ and use an analogy with a classical charged plasma to

compute $|\Psi^{\text{qh}}(\mathbf{y}; \cdot)|^2$ and Φ_σ , and then indeed conclude that there is, on top of geometric holonomies corresponding to a constant field $B/\mu = -b/\mu$ (i.e., effectively coupled to a fractional charge $+1/\mu$ that *reduces* the field), also topological exchange phases corresponding to the localized (but somewhat extended) attachment of fractional flux $-2\pi/\mu$ to the quasiholes. For a relatively recent review of the approach, including possible extensions to non-abelian scenarios (for which the quasihole map Ψ^{qh} is multidimensional), see [Bonderson et al. \(2011\)](#).

Transmuted Hamiltonian

[Forte \(1991\)](#) argued that the above approach is not necessarily sufficient to determine the anyonic statistics because, as we have noted above with the freedom of statistics transmutation, the knowledge of the specific Hamiltonian for the quasiholes is essential since that is what ultimately sets the scale of validity of any adiabatic treatment. Thus, a different approach was suggested in [Lundholm and Rougerie \(2016\)](#) and [Lambert et al. \(2022\)](#) to remedy this situation and supply the missing dynamical information, by considering quasiholes pinned to already present quantum particles.

In brief, one may consider the following idealized situation (see [Fig. 12](#)):

1. large 2D bath of noninteracting *fermions*, $N \gg 1$,
2. n tracers/impurities (initially can be either bosons or fermions), $1 \leq n \ll N$,
3. strong external transverse magnetic field, $b \rightarrow \infty$,
4. strong short-range repulsive bath-tracer interaction, at coupling $g \rightarrow \infty$.

Taking the bath particles $\mathbf{x}_j$ to have unit mass and unit negative charge, the tracers $\mathbf{y}_k$ to have mass m and charge $-q$, and allowing for interaction and trapping of tracers in a joint potential W , the Hamiltonian of the joint system is

$$H_{n \oplus N} := \frac{1}{2} \sum_{j=1}^N \left(-i\nabla_{\mathbf{x}_j} - b\mathbf{x}_j^\perp/2 \right)^2 + \frac{1}{2m} \sum_{k=1}^n \left(-i\nabla_{\mathbf{y}_k} - qb\mathbf{y}_k^\perp/2 \right)^2 + g \sum_{j=1}^N \sum_{k=1}^n \delta(\mathbf{x}_j - \mathbf{y}_k) + W(\mathbf{y}_1, \dots, \mathbf{y}_n),$$

acting on states

$$\Psi(\mathbf{y}_1, \dots, \mathbf{y}_n; \mathbf{x}_1, \dots, \mathbf{x}_N) \in L^2(\mathbb{R}^{2n}) \otimes L^2_{\text{asym}}(\mathbb{R}^{2N}).$$

If one takes $b \sim N$ and $N \gg n$, and assumes the bath then sits entirely in the LLL, thus forming a disk-shaped QH droplet of size ~ 1 , the Hilbert space is reduced to

$$\mathcal{H}_{\text{sym/asym}}^{n \oplus N} := L^2_{\text{sym/asym}}(\mathbb{R}^{2n}) \otimes \bigwedge^N_{\text{LLL}}$$

(allowing for either bosonic or fermionic tracers), with g.s.e.

$$E_{n \oplus N} := \inf_{0 \neq \Psi \in \mathcal{H}_{\text{sym/asym}}^{n \oplus N}} \langle H_{n \oplus N} \rangle_\Psi.$$

For $g \rightarrow \infty$, we then take as our ansatz for the ground state of the system a state in the kernel of the interaction:

$$\Psi_\Phi(\mathbf{y}; \mathbf{x}) := \Phi(\mathbf{w}) c^{\text{qh}}(\mathbf{w}) \Psi^{\text{qh}}(\mathbf{w}; \mathbf{z}), \quad (85)$$

with $\Phi \in L^2_{\text{sym/asym}}(\mathbb{C}^n)$, $c^{\text{qh}} > 0$ and

Fig. 12 Statistics transmutation in the QH setting. Bath particles (*red*) are repelled from tracers (*black*) by short-range interactions (*green*), and all particles move in an external homogeneous magnetic field (*blue arrows*). Subtracting the almost-homogeneous effective field generated by the bath as $b \sim N \gg 1$ then leaves a reduced/zero field plus remnant field (*blue disks*) at the holes punched in the bath by the tracers.

$$\int_{\mathbb{C}^n} |\Phi(w)|^2 dw = 1, \quad c^{\text{qh}}(w)^{-2} := \int_{\mathbb{C}^N} |\Psi^{\text{qh}}(w; z)|^2 dz,$$

ensuring the correct normalization $\int_{\mathbb{C}^{n+N}} |\Psi_\Phi|^2 dw dz = 1$.

The bath in LLL forces an *analytic* vanishing as $z_j \rightarrow w_k$, that is, $\mathbf{x}_j \rightarrow \mathbf{y}_k$. It suggests to take $\Psi^{\text{qh}} = \Psi_\mu^{\text{qh}}$ as above, corresponding to fractional filling $1/\mu$ of the LLL, or

$$\Psi_{\mu,p}^{\text{qh}}(w; z) := \prod_{k=1}^n \prod_{j=1}^N (w_k - z_j)^p \Psi_\mu^{\text{Lau}}(z),$$

thus also allowing for nonsimple quasiholes if $p > 1$.

It was conjectured in [Lundholm and Rougerie \(2016\)](#) and [Lambert et al. \(2022\)](#) that in this ansatz

$$\langle H_{n \oplus N} \rangle_{\Psi_\Phi} = \frac{bN}{2} + \langle H_n^{\text{eff}} \rangle_\Phi + \text{error}_\Phi(n/N), \quad (86)$$

for an effective **statistics-transmuted Hamiltonian** for the tracers:

$$H_n^{\text{eff}} := \frac{bn}{2m\mu} + \frac{1}{2m} \sum_{j=1}^n \left(-i\nabla_{y_j} - \left(q - \frac{p}{\mu} \right) \frac{b}{2} \mathbf{y}_j^\perp - \frac{p^2}{\mu} \mathbf{A}_j \right)^2 + W(y),$$

thus implying an effective renormalized charge $-q + p/\mu$ and shifted statistics parameter by $-p^2/\mu$.

In [Lambert et al. \(2022\)](#) it was proved mathematically that (86) is indeed a correct conclusion, with an error term of order $o(N)$ at fixed n and reasonable Φ , if $\mu = 1$ and $p = 1$, corresponding to transmutation of bosons into fermions and vice versa (cf. Section “Statistics transmutation in 2D”). Many crucial simplifications occur for these specific parameters, having to do with the Vandermonde structure of the state, and in the proof, it is also required that tracers have sufficient extra repulsion to not cluster too strongly at the diagonal set $\triangle_n$, which is ensured either by them being initially bosons and then eventually (free, if $q = 1$) fermions, or that W includes an additional and sufficiently strong intraspecies repulsion.

Impurities in the plane and polarons

Another route to statistics transmutation is to place tracers/impurities in a bath of bosons, such as the phonon vibrational modes of a crystal lattice, or photonic optical modes. Such systems are well known to enable transmutation of the impurities into **polarons**, that is, bound states of impurity particles and coherent states of phonons/photons ([Fröhlich, 1954](#); [Landau, 1933](#); [Pekar, 1946](#)). In [Yakoboylu and Lemesko \(2018\)](#) and [Yakoboylu et al. \(2020\)](#), it was observed that, subject to suitable external fields and rotation of such systems, the polarons can also transmute their statistics.

As an illustrative toy model, we consider a single bosonic collective degree of freedom:

$$[\hat{a}, \hat{a}^\dagger] = 1, \quad \hat{N} := \hat{a}^\dagger \hat{a}, \quad \text{with eigenstates } |N\rangle, \quad N \geq 0,$$

and an initial n -particle Hamiltonian

$$\hat{H}_0 = \sum_{j=1}^n (-i\nabla_{\mathbf{x}_j})^2 + W(\mathbf{x})$$

for bosons or fermions on $\mathcal{H}_0 = L^2_{\text{sym/asym}}(\mathbb{R}^{2n})$. Let us then define the interaction Hamiltonian

$$\hat{H}_{\omega,\gamma} := \hat{H}_0 + \omega \hat{a}^\dagger \hat{a} + \gamma \omega (F \hat{a}^\dagger + F^{-1} \hat{a}) + \gamma^2 \omega, \quad (87)$$

with two parameters $\omega > 0$ and $\gamma \in \mathbb{R}$. The interpretation of the terms added to $\hat{H}_0$ is that ω is the energy associated to an attachment or detachment of two units of flux or vorticity to each of the particles, which is done by the respective hopping terms with coupling $\gamma\omega$ and such that γ defines the ratio between these two effects. The last term is only a constant added for convenience.

We now denote $Z = \prod_{j < k} z_{jkl}$ and consider two possible choices for F (or their complex conjugates, depending on which way the orientation symmetry is to be broken):

1. $F = (Z/|Z|)^2 = U^2$ corresponding to **flux attachment**,
2. $F = Z^2$ corresponding to **vortex attachment**.

By acting with $F a^\dagger$ on the reference system $\mathcal{H}^0 = \mathcal{H}_0|0\rangle$, one obtains a ladder of Hilbert spaces of **composite bosons/fermions** (see [Fig. 13](#)):

$$\mathcal{H}^N := F^N \mathcal{H}_0 |N\rangle, \quad N = 0, 1, 2, \dots$$

Upon taking the “adiabatic limit” $\omega \rightarrow \infty$ at fixed γ , we claim that in the bottom of the spectrum of $\hat{H}_{\omega,\gamma}$ we then obtain a ladder of transmuted anyons with statistics parameter $\alpha = 2\gamma^2 + 2N$ ([Yakoboylu et al., 2020](#)). These anyons are either *interacting* by means of a

Fig. 13 Statistics transmutation in the polaron setting. An initial ladder of even-integer fluxes/vortices (composite bosons or fermions) is in the adiabatic limit transmuted into a ladder of fractional fluxes/vortices (anyons).

scalar potential $\sum_j A_j^2$ (for the more realistic, unitary choice $F = U^2$) or *free* (for the more algebraic, nonunitary choice $F = Z^2$, yielding a non-Hermitian Hamiltonian with $iA_j = \nabla_{x_j} \log Z$). Namely, the transformations

$$\hat{S} = F^{\hat{N}} = e^{\hat{N} \log F}, \quad \hat{U} = e^{-\gamma(\hat{a}^\dagger - \hat{a})}, \quad (88)$$

which diagonalize $\hat{H}_{\omega, \gamma}$,

$$\hat{U}^{-1} \hat{S}^{-1} \hat{H}_{\omega, \gamma} \hat{S} \hat{U} = \omega \hat{a}^\dagger \hat{a} + \sum_{j=1}^N \left[-i \nabla_{x_j} + 2A_j(\hat{a}^\dagger - \gamma)(\hat{a} - \gamma) \right]^2 + W(x),$$

create coherent-state mixtures

$$\hat{S} \hat{U} |0\rangle = e^{\gamma^2/2} \sum_{N=0}^{\infty} \frac{(-\gamma)^N}{\sqrt{N!}} F^N |N\rangle \quad (89)$$

over the initial ladder of integer composites and enable a shift of the expected amount of flux/vorticity by $\alpha_0 = 2\gamma^2 \geq 0$, possibly to noninteger values. This transmutation procedure has indeed been used (with the choice $F = Z^2$) to compute the numerical spectra seen in Fig. 4.

A possible plane polaron model with the above form is obtained upon applying a constant magnetic field $\mathbf{B}$ and shifting to a counter-rotating frame at half the cyclotron frequency $\Omega = B/(2m)$ (cf. Fig. 14, upper):

$$\hat{H}_N = \frac{1}{2m} \sum_{j=1}^n \hat{p}_j^2 + W^\Omega(x) + \sum_{\mathbf{k}} \omega_{\mathbf{k}}^\Omega \hat{b}_{\mathbf{k}}^\dagger \hat{b}_{\mathbf{k}} + \sum_{\mathbf{k}} \lambda_{\mathbf{k}}(x) \left(e^{-i\beta_{\mathbf{k}}(x)} b_{\mathbf{k}}^\dagger + e^{i\beta_{\mathbf{k}}(x)} b_{\mathbf{k}} \right),$$

for phonon vibration modes $b_{\mathbf{k}}$, $\mathbf{k} \in \mathbb{R}^2$ with dispersion $\omega_{\mathbf{k}}^\Omega$ (which is their bare dispersion shifted by their angular momentum coupled to Ω), and phonon-impurity interaction parameters $\lambda_{\mathbf{k}}$, $\beta_{\mathbf{k}}$. For $n = 2$ and a suitable interaction, realizable within the Fröhlich plane polaron model with quasi-2D Coulomb forces (Yakaboylu et al., 2020), the emergent gauge field

$$\alpha A_j(x) \approx \langle -i \nabla_{x_j} \rangle_{\hat{S} \hat{U} |0\rangle} \approx - \sum_{\mathbf{k}} (\lambda_{\mathbf{k}}(x) / \omega_{\mathbf{k}}^\Omega)^2 \nabla_{x_j} \beta_{\mathbf{k}}(x) \quad (90)$$

Fig. 14 Two possible experimental probes for emergent statistics transmutation: rotating plane in which Fröhlich polarons turn into anyons and the exchange of linear molecules. Upper, from Yakaboylu E, Ghazaryan A, Lundholm D, Rougerie N, Lemeshko M, and Seiringer R (2020) Quantum impurity model for anyons. *Physical Review B* 102: 144109; lower, from Brooks M, Lemeshko M, Lundholm D, and Yakaboylu E (2021b) Molecular impurities as a realization of anyons on the two-sphere. *Physical Review Letters* 126: 015301

is then approximately of the correct Aharonov–Bohm type and such as to transmute the statistics by $\alpha \approx \alpha(\Omega)$, ascertained by the system’s correlations to the collective reference rotation/field.

Impurities on the sphere and angulons

A similar approach (Brooks et al., 2021a, b) can be taken for particles moving effectively on a sphere $\mathbb{S}^2$, namely, one may, for example, replace the planar kinetic energy (4) by the rotation energy

$$T_{\text{rot}} = \sum_{j=1}^n \mathbf{L}_j^2 \quad (91)$$

(with units normalized suitably) of n identical linear molecules (cf. Fig. 14, lower). The resulting model for the Hamiltonian coupled to a bath of rotational angular momenta is called an **angulon** model (Schmidt and Lemeshko, 2015). This transmutation method has also been used to compute the energy spectrum of two anyons on a sphere (Brooks et al., 2021b); cf. (Ouvry and Polychronakos, 2019; Polychronakos and Ouvry, 2020) and see Einarsson (1992) concerning anyons in various topologies.

Other emergent models for anyons

Other approaches to investigate statistics transmutation in the QH setting include effects of anyonic shifted angular momentum on the energy spectrum (Cooper and Simon, 2015), and on pair correlation and other aspects of the density (Dubček et al., 2018; Graß et al., 2020; Morampudi et al., 2017; Umucalilar et al., 2018; Zhang et al., 2014), including non-abelian scenarios (Baldelli et al., 2021; Zhang et al., 2015). Emergent anyons can also be expected on spin networks and lattices (Bachmann, 2017; Bachmann et al., 2020, 2023). Certain classes of non-abelions have been proposed to emerge in the physics of neutrons and neutron stars (Masaki et al., 2023). Even in the quantum gravity context might we expect non-abelions, as they can capture the relevant degrees of freedom on the black-hole event horizon (Pithis and Ruiz Euler, 2015).

Conclusion

In light of recent experiments concerning anyons (Bartolomei et al., 2020; Fan et al., 2022; Google Quantum AI and Collaborators, 2022; Nakamura et al., 2020), it is increasingly important to gain a firm theoretical understanding of the basic properties of the anyon gas. We have here focused on its precise definition in typical ideal and nonideal contexts, its most basic physics as regards the

connection between exchange and exclusion statistics, as well as its inevitable emergence in a few conceptually simple scenarios involving relatively well-understood bosonic and fermionic systems with manifest breaking of orientation symmetry, such as the rotated polaron and the quantum Hall setup.

In preparation for future experiments and theoretical research, one could make a few observations and highlight some potential obstacles. First, it is hoped that accurate density functional theories for large systems of anyons will provide more robust, detectable signatures, such as spatial and momentum density profiles, as compared to the typically extremely fragile phases probed by interferometry (cf., Camino et al., 2005; Nakamura et al., 2020). Second, the development of impurity models and the pinning of quasiholes, fluxes, and vortices to already well-understood quantum particles promises to eliminate some of the ambiguities inherent in conventional Berry phase and adiabatic treatments (cf., Forte, 1991; Jain, 2007; Lambert et al., 2022; Lundholm and Rougerie, 2016; Myrheim, 1999). Third, with the steadily growing literature on anyons and an increasing interest in their fascinating physics, even from the general public, it is important to be aware of potential confusion on how the term “anyon” is used. Hopefully, this overview has helped to clarify both the nontrivial relationship between exchange and exclusion statistics and the crucial differences between (a) the **choice or construction** of a concrete braid group representation $\rho_N : B_N \rightarrow U(\mathcal{F}_N)$ (algebra, kinematics, or simply an action of a permutation on a system); (b) its **practical realization** such as by means of motion of classical parameters (magnetics, or computation using a classical or quantum computer; cf., Noh et al., 2020); and (c) **actual anyons** (or bosons or fermions) endowed with quantum kinetic energy $\hat{T}_{\rho_N}$ (geometroynamics), uncertainty and exclusion.

Acknowledgments

The study of the magnetic TF functional for anyons was done in collaboration with Dinh Thi Nguyen, following helpful discussions with Nicolas Rougerie and Théotime Girardot. Further, I thank the editor Tapash Chakraborty for the timely invitation to write this overview, as well as Vincent Cavalier, Ask Ellingsen, Gerald Goldin, and Wolfgang Staubach for useful comments on the manuscript. I am thankful to numerous other colleagues for insightful discussions on this topic over the last 13 years, in particular Jan Philip Solovej, who raised my interest in it, as well as Eddy Ardonne, Morris Brooks, Michele Correggi, Romain Dubosq, Luca Fresta, Jürg Fröhlich, Thors Hans Hansson, Gaultier Lambert, Simon Larson, Jon Magne Leinaas, Tomasz Maciazek, Per Moosavi, Luca Oddis, Stéphane Ouvry, Viktor Qvarfordt, Robert Seiringer, Andrea Trombettoni, Susanne Viefers, and Enderalp Yakaboylu. The research project was funded by the Swedish Research Council (grant no. 2021-05328, “Mathematics of anyons and intermediate quantum statistics”).

Abstract

This is a pedagogical introduction to abelian and non-abelian anyons, where we discuss basic concepts in anyon physics, such as the idea of quantum statistics and introduce the idea of the braid group. We explain what is meant by braiding and fusing of anyons. We then briefly discuss non-abelian anyons where we use the one dimensional Kitaev model as a prototypical example to produce Majorana modes at the edge. We then explicitly show how braiding these Majoranas lead to rotations in the ground state manifold. We end with a brief discussion of the future prospects of the field.

Key points

- Phases of wavefunctions under adiabatic exchange
- Configuration space of a many-particle system
- Unitary representation for the group of inequivalent paths
- Braid group and Yang-Baxter relations
- Fusion rules
- Non-abelian anyons and ground state degeneracy
- Kitaev's one-dimensional model of Majoranas
- Statistics of Majorana modes

Introduction

What are anyons? While it is generally known that all particles in nature come in two classes, fermions and bosons, the name 'anyon' was coined by Wilczek (Wilczek, 1982) to indicate a new kind of particle that belongs to neither class. Fermions are particles with $1/2$ integer spin obeying Fermi-Dirac statistics, which means that two or more identical fermions cannot co-exist at the same point in space or occupy the same energy level. Bosons, on the other hand, are integer spin particles obeying Bose-Einstein statistics, and can crowd together in the same space or occupy the same energy level. Unlike bosons and fermions, 'anyons' were initially just conjectured as theoretical possibilities (Leinaas and Myrheim, 1977) as generalizations of what could happen when particles are intermediate between bosons and fermions, and obeyed a different kind of statistics. However, they shot into prominence in the 1980s when it was realized (Laughlin, 1983) that quasi-particle excitations in the fractional quantum Hall effect (Tsui et al., 1982) had fractional charges and most likely fractional statistics. The fractional charges were seen (De Picciotto et al., 1997) (in noise experiments in the 1990s, but it is only very recently that the fractional statistics obeyed by these quasi-particles have been convincingly seen (Nakamura et al., 2020).

Quantum statistics

Very naively, 'anyons' are particles obeying 'any' statistics. Clearly, this begs the question 'what are 'any' statistics? To answer this, we need to start with the notion of phases and statistics under exchange of identical or indistinguishable particles in quantum mechanics. The term 'exchange statistics' refers to the phase picked up by a wave-function when two identical particles are exchanged. But this definition is slightly ambiguous. Does statistics refer to the phase picked up by the wave-function when all

the quantum numbers of the particles are exchanged (i.e., under permutation of the particles) or the actual phase that is obtained when two particles are adiabatically transported giving rise to the exchange? In three dimensions, these two definitions are equivalent but not in two dimensions. In quantum mechanics, we deal with interference of paths of particles and hence, it is the second definition which is more relevant, and we will show how it can be different from the first definition.

Recall that in quantum mechanics, the probability amplitude to go from one space-time point to another is given by

$$A = \sum_{\text{paths}} e^{iS}, \quad (1)$$

where $S = \int \mathcal{L} dt$ is the action for the particular trajectory or path. In other words, quantum mechanically, we need to include all possible paths between the initial and final points of the trajectory (See Fig. 1). But most of these paths will interfere destructively with each other and hence will not contribute to the probability amplitude. The only exception is the classical path and the paths close to it, which interfere constructively with the classical path i.e., the most important contribution will be from the classical path. So the amplitude for a system of two particles that moves from $(\mathbf{r}_1(t_1), \mathbf{r}_2(t_1))$ to $(\mathbf{r}_1'(t_2), \mathbf{r}_2'(t_2))$ is given by

$$A = \sum_{\text{paths}} e^{i \int_{t_1}^{t_2} dt \mathcal{L}[\mathbf{r}_1(t), \mathbf{r}_2(t)]}. \quad (2)$$

Let us first consider the statistics under exchange of two particles in three dimensions. If the two particles are identical, then there are two classes of paths (see Fig. 2 where we have assumed that time runs vertically upwards). How do we see this? If we use the convention that we always refer to the position of the first particle first and the second particle second, then we see that the final configuration remains the same whether we have $(\mathbf{r}_1(t_2), \mathbf{r}_2(t_2))$ or $(\mathbf{r}_2(t_2), \mathbf{r}_1(t_2))$ because the two particles are identical. Even though the particles are exchanged in one path and not in the other, the final configuration is the same. Essentially, this means that the Hilbert space is halved as compared to the case of distinguishable particles. Another way of looking at this is to say that the configuration space (which is the name for the space of the states) has been split into topologically inequivalent sectors - one without exchange of the particles and one with exchange of the particles - which cannot be deformed into one another continuously.

To explain this further, and pictorially, let us think in terms of the center of mass ($\mathbf{R} = (\mathbf{r}_1 + \mathbf{r}_2)/2$) and relative coordinates ($\mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2$). We note that the center of mass motion is the same for both the paths, but the relative coordinate changes for both the paths. Also, since the CM motion moves both the particles together, it is independent of any possible phase under exchange. So here, we will only focus on the relative coordinate $\mathbf{r}$. For convenience in visualizing the configuration space, let us keep $|\mathbf{r}|$ fixed and non-zero, i.e., the two particles do not intersect. Then, the vector $\mathbf{r}$ takes values on the surface of the sphere.

Fig. 1 Sum over paths from $q(t_1)$ to $q(t_2)$.

Fig. 2 Direct and exchange paths.

Fig. 3 Paths in three dimensional configuration space with fixed radius.

Now let us draw the paths in configuration space as shown in Fig. 3. It is clear that the paths can only move along the surface of the sphere as the two particles move, since $|\mathbf{r}|$ is fixed. But once they get back to their original positions or get exchanged, since they are indistinguishable, the path is closed. In other words, closed paths on the surface of the sphere are formed by the particles coming back to their original positions (no exchange) or going to the antipodal point ($\mathbf{r} \rightarrow -\mathbf{r}$ or getting exchanged). But if we exchange the particles once again, then $\mathbf{r}$ comes back to itself, after having gone around the sphere once. In terms of diagrams, this is shown in Fig. 3C. It can also retrace its path, but that will be trivially equivalent to no exchange like in Fig. 3A. Since we have eliminated coincident points, the wave-function is non-singular and well-defined at all points in the configuration space, and consequently on the surface of the sphere. So the phase picked up by the wave-function is also well-defined and does not change under continuous deformations of the path. Let us consider the possible phases of the wave-function when the motion of the particles is along each of the three paths, – A (no exchange), B (single exchange) and C (two exchanges) – depicted in Figs. 3A–C. Path A is a closed path which does not involve any exchange and can clearly be shrunk to a point. Hence, the wave-function cannot pick up any phase other than unity. Path B involves the exchange of the two particles and goes from a point on the sphere to its diametrically opposite point. Since the two end points are fixed, this path cannot be shrunk to a single point. So this exchange can have a non-trivial phase in the wave-function. However, path C which forms a closed loop on the surface and involves two exchanges can be continuously shrunk to a point by imagining the path to be a physical string looped around a sphere. So this again cannot pick up any phase. Let η be the phase picked up under a single exchange. Since two exchanges are equivalent to no exchange, $\eta^2 = +1 \Rightarrow \eta = \pm 1$. Hence, the only statistics possible in three dimensions are Fermi statistics or Bose statistics.

With slightly more mathematical rigor, one can say that the configuration space of relative coordinates is given by $(\mathbb{R}_3 - \text{origin})/\mathbb{S}_2$. Here $\mathbb{R}_3$ is just the three dimensional Euclidean space spanned by the relative coordinate $\mathbf{r}$. We subtract out the origin because we have assumed that paths do not cross (which is true for all particles other than bosons, because of hard core repulsion and for bosons, it is irrelevant whether or not they cross, because the exchange phase is always unity). The division by $\mathbb{S}_2$ where $\mathbb{S}_2$ is the symmetric group or permutation group is because of the identification of $\mathbf{r}$ with $-\mathbf{r}$, which, in turn, is because the particles are indistinguishable. To study the phase picked up by the wave-function of a particle as it goes around another particle, we need to classify all paths in this configuration space. The claim, from the pictorial analysis above, is that there are just two classes of paths. Mathematically, this is expressed in terms of the first homotopy group Π_1 of the space, which is the group of inequivalent paths (paths not deformable to each other), passing through a given point in the space, with group multiplication being defined as traversing paths in succession and group inverse as traversing a path in the opposite direction. Thus

$$\Pi_1(\mathbb{R}_3 - \text{origin})/\mathbb{Z}_2 = \Pi_1(\mathbb{RP}_2) = \mathbb{Z}_2 \quad (3)$$

where $\mathbb{RP}_2$ stands for real projective space and is the notation for the surface of the sphere with diametrically opposite points identified and $\mathbb{Z}_2 = (1, -1)$ is a group of just two elements.

In terms of the path integral, the amplitude (for 2 particles) can now be written as

$$A = \sum_{\text{regular paths}} e^{i \int_{t_1}^{t_2} dt \mathcal{L}[\mathbf{r}_1(t), \mathbf{r}_2(t)]} + e^{i\phi} \sum_{\text{exchange paths}} e^{i \int_{t_1}^{t_2} dt \mathcal{L}[\mathbf{r}_1(t), \mathbf{r}_2(t)]} \quad (4)$$

where we have introduced a phase between the regular and exchange paths. But since exchanging twice corresponds to a regular path, $e^{2i\phi} = 1$, with $\phi = 0$ corresponding to bosons and $\phi = \pi$ corresponding to fermions. This can now be easily generalized to N particles with

$$A = \sum_{g \in G} \rho(g) \sum_{\text{paths}} e^{i \int_{t_1}^{t_2} dt \mathcal{L}[\mathbf{r}_1(t), \mathbf{r}_2(t)]} \quad (5)$$

Here G is the fundamental group of paths, which, as explained above is just the group of inequivalent paths, which (in $3 + 1$ dimensions) is just $\mathbb{S}_2$ for 2 particles, and generalizes to $\mathbb{S}_N$ for N particles. $\rho(g)$ is a unitary representation of G . It is easy to check

that there are only two possible one-dimensional representations of G in $3 + 1$ dimensions either $\rho(g) = 1$ for all g (bosons) or $\rho(g) = +1/-1$ for even or odd number of exchanges of the N particles (fermions). The story changes if we allow for higher dimensional representations of $\mathbb{S}_N$, but before we do that, let us see what happens in $2 + 1$ dimensions.

What changes in two dimensions? The key point is that the topology of the configuration space is now different. In two spatial dimensions, the configuration space of the relative coordinates is given by $(\mathbb{R}_2 - \text{origin})/\mathbb{S}_2$. Just as before, for ease of visualization, we can keep the magnitude of the relative coordinate fixed, so that configuration space can be represented by a circle, and since the particles are indistinguishable, diametrically opposite points are identified (see Figs. 4A–C). Here, however, several closed paths are possible. The path A that involves no exchanges can obviously be shrunk to a point, since it only moves along the circle and back. But path B that exchanges the two particles is non-contractible since the end-points are fixed. But even path C, where both the solid and dashed line are followed in the clock-wise direction (or anti-clockwise direction) cannot be contracted to a point. This is easily understood by visualizing the paths as physical strings looping around a cylinder. Thus, if η is the phase under single exchange, η^2 is the phase under two exchanges, η^3 is the phase under three exchanges and so on. All we can say is that since the modulus of the wave-function remains unchanged under exchange, η has to be a phase $-\eta = e^{i\theta}$. This explains why we can get ‘any’ statistics in two dimensions.

The distinction between the paths in two and three dimensions can also be seen as follows. In three dimensions, the loop that is formed by taking a particle all around another particle (two exchanges) can be lifted off the plane and shrunk to a point as shown in Fig. 5. This is not possible if the motion is restricted to a plane, as long as we disallow configurations where two particles are at the same point (removal of the origin).

The mathematical crux of the distinction between configuration spaces in two and three dimensions, is that the removal of the origin in two dimensional space, makes the space multiply connected (unlike in three dimensional space, where removal of the origin keeps it singly connected). So it is possible to define paths that wind around the origin. Mathematically, we can say that

$$\Pi_1((\mathbb{R}_2 - \text{origin})/\mathbb{S}_2) = \Pi_1(\mathbb{RP}_1) = \mathbb{Z} \quad (6)$$

Fig. 4 Paths in two dimensional configuration space with fixed radius.

Fig. 5 Path of A around B being lifted off the surface and shrunk to a point.

where $\mathbb{Z}$ is the group of integers under addition. $\mathbb{RP}_1$ is just the notation for the circumference of a circle with diametrically opposite points identified. The different paths are labelled by integer winding numbers.

So in terms of path integrals, we now see that paths starting and ending at the same positions (up to exchanges due to indistinguishability) can be divided into an infinite number of classes, all distinct. So the path integral for the total amplitude is now given by

$$A = \sum_{g \in G} \rho(g) \sum_{\text{paths}} e^{i \int_{t_1}^{t_2} dt \mathcal{L}[\mathbf{r}_1(t), \mathbf{r}_2(t)]} \quad (7)$$

where G now is the group of inequivalent paths in $2 + 1$ dimensions (called the braid group $\mathbb{B}_2$) and $\rho(g)$ now gives the possible unitary representations of $\mathbb{B}_2$ in $2 + 1$ dimensions. Unlike in $3 + 1$ dimensions, we can now get a different phase each time we exchange the particles, so that

$$A = \sum_{\text{direct paths}} e^{iS} + e^{i\phi} \sum_{\text{single exchange}} e^{iS} + e^{2i\phi} \sum_{\text{two exchanges}} e^{iS} + \dots \quad (8)$$

Here $\phi = 0, \pi$ give the usual bosons and fermions, but since in general, $e^{in\phi} \neq 1$ for any n , ϕ can be anything and as we said earlier, ‘any’ statistics of fractional statistics are possible in two dimensions. It is now easy to see that unlike for fermions and bosons, generalizing this to N particles is not trivial. At each time slice after the exchange of any two particles, the configuration depends on whether the particles have been exchanged in a clock-wise or counter clock-wise direction, or more generally, on the winding number of the exchange. So the entire history of the exchanges of every pair becomes relevant, and the problem of even free anyons becomes as complicated as the problem of particles, all of which are strongly interacting with one another.

Braiding and fusing of anyons

Anyons obey braid group statistics

The distinction between the phase of the wave-function when the quantum numbers of the particles are exchanged and the phase obtained under adiabatic transport of particles should now be clear. Under the former definition, the η^2 after two exchanges is always unity, whereas the phase under the latter definition has many more possibilities at least in two dimensions. Mathematically, the first definition classifies particle under the permutation group $\mathbb{S}_N$, whereas the second one classifies particles under the braid group $\mathbb{B}_N$. The permutation group $\mathbb{S}_N$ is the group formed by all possible permutations of N objects with group multiplication defined as successive permutations and group inverse as undoing the permutation. It is clear that permuting two objects twice brings the system back to the original configuration. Thus particles that transform as representations of the permutation group can only be bosons or fermions.

On the other hand, when we adiabatically exchange two particles, we can visualize the process as paths in space-time with time being the vertical axis and space being the horizontal axis as shown in Fig. 2. The particles can circle around each other and form closed paths by coming back to their original positions (up to permutations of the positions). The adiabatic exchange of particles classifies particles under the braid group. As we saw earlier, even under adiabatic exchange, in three spatial dimensions, we only have fermions or bosons, whereas in two dimensions, there are many other possibilities. Formally, the braid group $\mathbb{B}_N$ is the group of inequivalent paths that occur when adiabatically transporting N particles. Since they represent a configuration of N particles, at some particular time (say $t = 0$), evolving to a configuration of N particles at some later time $t = T$, the world lines cannot cross each other or form knots around each other or loop back. At each time, we want to have only N particles. Each history or set of trajectories of the N particles becomes a braid. For example, in Fig. 6, we show an example of some elements of the braid group $\mathbb{B}_4$, which is the braid group of 4 particles. (We have restricted the particles to be on a single line for ease of depiction). Exchanges of neighboring particles (by some counting rule, since the particles are in two dimensional space) form the generators of the group. For instance, the generators of the group $\mathbb{B}_4$ are given in Fig. 7 and are denoted as σ_j , $j = 1, 2, 3$. σ_j describes exchange of j^{th} particle with $(j + 1)^{\text{th}}$ particle in a counter-clockwise direction (by definition), so that the clockwise exchange is denoted by $(\sigma_j)^{-1}$. The identity element is given by σ_0 where there is no exchange, and group inverse by the clockwise exchange $(\sigma_j)^{-1}$ as shown in Fig. 8. Group multiplication

Fig. 6 Elements of the braid group $\mathbb{B}_4$.

Fig. 7 The three generators of the braid group $\mathbb{B}_4$.

Fig. 8 The identity and the inverse of the generator σ_1 .

Fig. 9 Group multiplication.

is defined as following one trajectory by another in time as shown in Fig. 9. Note that we have put crosses on the time-lines which are identified (are at equal times) in the figure. It is now easy to check that $(\sigma_j)(\sigma_j)^{-1} = \sigma_0$ as shown in Fig. 10 (without the crosses). It is also easy to see that $(\sigma_1)^n \neq \sigma_0$ for any n , which is the reason that ‘any’ statistics are allowed in two dimensions. (See Fig. 11).

We will end this subsection by mentioning the two defining relations satisfied by the generators of the braid group.

$$\sigma_i \sigma_j = \sigma_j \sigma_i, \quad |i - j| \geq 2$$

$$\sigma_j \sigma_{j+1} \sigma_j = \sigma_{j+1} \sigma_j \sigma_{j+1} \quad (9)$$

The second one is called the Yang-Baxter relation. Both these relations can be easily checked pictorially (as we show in Fig. 12 for the generators of $\mathbb{B}_4$).

Fig. 10 Product of σ_1 and $(\sigma_1)^{-1}$ giving rise to identity.

Fig. 11 $(\sigma_1)^n \neq \sigma_0$.

Fig. 12 Yang-Baxter relations.

Fig. 13 Different elements of the braid group, but same element of the permutation group.

It should be clear by now that the braid group leads to a much finer classification than the permutation group. For instance, the two elements shown in Fig. 13 are different elements of the braid group, but the same element of the permutation group. So the quantum theory of anyons has the quantum states of the anyons transforming as unitary representations of the braid group. Abelian anyons form one-dimensional representations of the braid group. There are an infinite number of such representations, because under exchange, the phase that is picked up is $e^{i\theta}$ and θ can take any value $\theta = 0$ and $\theta = \pi$ represent bosons and fermions respectively. We will discuss non-abelian representations in the last section.

Note that if we do want to understand adiabatic exchange of particles in the Hamiltonian formulation without invoking path integral ideas, we need to pin down the particles by using a confining potential - i.e., by putting them in a box-

$$H = \sum_i \frac{\mathbf{p}_i^2}{2m} + \sum_i V_{\text{box}}(\mathbf{x}_i - \mathbf{R}_i) \quad (10)$$

The particles can now be moved around by changing $\mathbf{R}_i$ as a function of time. Since the particles are identical, exchanges are equivalent to closed paths, and do not depend on the geometry of the paths $\mathbf{R}_i(t)$ involved. So the statistics of the particles under exchange can be found by computing the Berry phase when the particles are exchanged. However, here, we shall basically stick to the path integral formalism.

In recent times, the focus on the dimensionality of space-time has been reduced. Instead, it has been realized that in any dimension, as long as constraints can be imposed to make every exchange of the paths in configuration space well-defined (as automatically happens in two dimensions), anyons are possible. The important point is that the particles transform as representations of the braid group.

Anyon composites or fusion rules

Before we go on to non-abelian anyons, we need to introduce one more concept and that is the idea of what happens when we bring two anyons close together. Does this form a new kind of composite particle? We know that a composite particle made of two bosons will still form a boson, but a composite particle made of two fermions will obey bosonic statistics and not fermionic statistics. What happens with anyons?

To understand this, the easiest way is to think of a physical model for the anyon. We imagine the anyon to be a charge bound to a very thin solenoid or flux-tube carrying a flux ϕ . Now we consider taking one such bound charge-flux particle around another. Due to the Aharonov-Bohm effect, (Aharonov and Bohm, 1959) we know that the phase acquired by the charge encircling a solenoid is given by $e^{iq\phi/\hbar}$. Equivalently, by the Aharonov-Casher effect (Aharonov and Casher, 1984), we know that the flux ϕ going around a charge q will also acquire a phase $e^{iq\phi/\hbar}$. So taking one-charge flux composite completely around the other gives rise to a phase of $e^{2iq\phi/\hbar}$. But since taking one particle completely around another is equivalent to two exchanges, we see that the phase acquired under an exchange of the charge-flux composite is $e^{iq\phi/\hbar}$. So the anyon parameter $\theta = q\phi/\hbar$ and is zero for bosons and π for fermions.

Now, we can try and see what happens when we bring two anyons together. The composite particle will now have a charge of $2q$ and a flux of 2ϕ . So the appropriate anyon that is formed will have a statistics parameter given by $4q\phi/\hbar$ since both the flux and the charge have been doubled. This is now a new or different kind of anyon with the sum of both the fluxes and the charges. This idea of bringing together anyons to form a new kind of particle is called fusion. Note that it is not really necessary for the two anyons to actually form a bound state. If they are brought close together and form a 'cluster,' then the cluster behaves like a single particle.

Non-abelian anyons

Generalities

Now let us consider higher dimensional representations of the braid group $\mathbb{B}_N$. Higher dimensional representations can occur typically when we have degeneracies in the system. Let us consider a set of M degenerate (orthonormal) states of N particles at fixed positions, $\psi_\alpha(\mathbf{r}_1, \dots, \mathbf{r}_N)$. In this basis, when we adiabatically exchange the position of two particles at $\mathbf{r}_1$ and $\mathbf{r}_2$, the original state gets unitarily rotated to another state in the same subspace. In other words,

$$\psi_\alpha(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N) \rightarrow U(\sigma_1) \psi_\alpha(\mathbf{r}_2, \mathbf{r}_1, \dots, \mathbf{r}_N) \quad (11)$$

where $U(\sigma_1)$ is an $M \times M$ unitary matrix acting in the space of degenerate states. U depends on the braiding operator σ_1 which exchanges particles 1 and 2. Similarly, we can get

$$\psi_\alpha(\mathbf{r}_j, \mathbf{r}_{j+1}) \rightarrow U(\sigma_j) \psi_\alpha(\mathbf{r}_{j+1}, \mathbf{r}_j) \quad (12)$$

for any other exchange of a pair of particles. Since, in general the $U(\sigma_j)$ for different values of j do not commute with each other, the particles obviously obey non-abelian braid group statistics. Clearly, we need at least a degeneracy of 2 to get non-abelian braiding; else, the U matrices are merely phases which commute with one other.

Non-abelian anyons were first introduced in the context of conformal field theory and the fractional quantum Hall effect (Moore and Read, 1991). The relevance to quantum computation comes from the fact that not only does braiding cause rotations in the degenerate subspace, the only way to go cause rotations in this subspace (at low enough energies, so that we cannot access any other high energy state) is via braiding. So the different states in the subspace are protected from local perturbations (as long as they do not have matrix elements within the degenerate subspace). You can go to another state in the system, only by braiding which is a non-local process, sensitive only to the topology of the trajectory and not to local geometry or dynamics. Hence, the system is decoherence free.

So how does one use non-abelian anyons for quantum computation? We first need to construct the qubit. Here, these are just the set of degenerate states - 2 for qubits, 3 for qutrits, etc. This is initialized by preparing it in a particular way, so that we know the initial state. We then perform unitary operations on the state by exchanging particles in some specified way. The resulting evolution is dependent only on the braiding and not on how the exchanges were carried out in detail. Then one can measure the state of the qubit at the end of the operation. We also do not need to worry about whether or not the particles were brought back to the exact positions, because often the initialization and measurement techniques involve creating, separating and bringing together quasi-particles, so that there are no open braids and the full process is completely topological. This is why generically, topological quantum computation using non-abelian anyons is called fault-tolerant.

With this motivation, let us continue with our study of non-abelian anyons. We first need a list of particles with their charges. Note that here by charges, we mean topological charges. In a condensed matter system, one can have quasi-particle excitations which are either local or which are topological. A simple example is that of spin flip excitations in an Ising model in one dimension as shown in Figs.14A and B. A single spin-flip (or even a few spin flips) is a local excitation and is equivalent to the identity as far as particle type is considered. But a domain wall is a topological excitation that is protected by the boundary conditions and cannot be removed by local perturbations. As long as the edge spins are kept fixed and opposite, there will be at least one domain wall or one topological charge in the system. In this example, a local excitation (where the edge spins are kept the same) can be considered as two domain walls. So here one can only get topological charges 0 or 1, because any two topological charges are considered equivalent if they differ by local charges (obtained by applying local operators). But more generally, even the number of types of topological charges that you can get in a theory is a topological property and is related to the number of degenerate states. (In the

Fig. 14 The first denotes a local excitation, since it can be removed by flipping two spins locally, whereas the second one is a topological quasi-particle since it is protected by the boundary conditions which are fixed.

example, we have considered here, with a domain wall, the assumption is that, in the large system limit, the states with and without domain walls are approximately degenerate).

To write down a theory of non-abelian anyons, the ingredients we require are the following (Preskill, 2004)

- (a) a list of the topological charges
- (b) fusion rules for fusing the topological charges (and its inverse, the splitting rules)
- (c) braiding rules for exchanging two particles

So if we list the topological particles in our system as $a, b, c \dots$, then the fusion rules are given by

$$a \times b = \sum_c N_{ab}^c c \quad (13)$$

where $N_{ab}^c \geq 1$. This equation simply means that if $N_{ab}^c = 0$, then the particle c is not obtained and if $N_{ab}^c = 1$, then the particle c is obtained as a fusion product and if $N_{ab}^c > 1$, then c can be obtained in N_{ab}^c ways. Here, a, b, c are just labels of the different kinds of particles. For abelian anyons, an anyon with statistics parameter α_1 will fuse with an anyon with statistics parameter α_2 to yield a specific anyon with statistics parameter α_3 and $N_{\alpha_1 \alpha_2}^{\alpha_3} = 1$ and is otherwise zero. But this is not true for non-abelian anyons. The fusing of two anyons could lead to different types of particles with different probabilities. In that sense, fusion of particles is like a measurement. Given two abelian anyons a and b , their fusion is well-defined and leads to a unique answer. But for non-abelian anyons, it does not lead to a single answer. The integers N_{ab}^c define the probabilities of the outcome. The simplest non-abelian model will have $N_{ab}^c \neq 0$ for at least two distinct values of c . The Hilbert space of two (or more) dimensions formed from these distinct outcomes of fusing two particles is known as the topological Hilbert space of the pair of non-abelian anyons.

Now, let us consider what happens when we have many non-abelian anyons. For abelian anyons, each time you bring in a new particle, the fusion rules give you only one possible outcome. But for non-abelian anyons, since even two anyons can have more than one outcome, a third anyon can fuse with either of the outcomes and again give rise to more possible outcomes. So one can get many fusion paths, since fusion is not unique. Since sometimes, different paths can lead to the same outcomes, there are consistency conditions that need to be satisfied called pentagon equations. Once we also include braiding matrices in the game, there are also consistency conditions called hexagon equations which need to be satisfied.

However, instead of going further ahead with the abstract analysis, we will now change gears and study a concrete model with non-abelian excitations. This is the Kitaev one-dimensional toy model with unpaired Majorana fermions. We will explicitly show that these Majorana fermions obey non-abelian statistics under exchange.

Kitaev model in one dimension

The Hamiltonian for the Kitaev model in one dimension is given by (Kitaev, 2001)

$$H = -\mu \sum_{x=1}^N n_x - \sum_{x=1}^{N-1} (t c_x^\dagger c_{x+1} + \Delta c_x c_{x+1} + h.c.) \quad (14)$$

where c_x represents spinless fermions on site x , t is the amplitude of hopping to nearest neighbor sites, and Δ is the superconducting parameter and denotes p -wave pairing - p wave because the electrons are of the same kind (spinless or equivalently same projection of spin) - on nearest neighbor sites. μ is the chemical potential and $n_x = c_x^\dagger c_x$ is the density operator, so that $N = \sum_x n_x$. Since by a redefinition of the phase of the fermions, any phase in the superconducting order parameter can be absorbed, without loss of generality, we can take Δ to be real and positive.

Now, let us rewrite the Hamiltonian in terms of new operators called Majorana operators.

$$\begin{aligned} c_x &= \frac{1}{2} (\gamma_{A,x} - i\gamma_{B,x}) \\ c_x^\dagger &= \frac{1}{2} (\gamma_{A,x} + i\gamma_{B,x}) \end{aligned} \quad (15)$$

This implies that $\gamma_{A,x} = c_x + c_x^\dagger$ and $\gamma_{B,x} = i(c_x^\dagger - c_x)$ are hermitean (self-conjugate) operators. This is the definition of Majorana operators.

Now, let us look at some properties of these Majorana modes. We can check that they are fermions, in the sense that they anti-commute. More precisely, they satisfy the algebra given by

$$\{\gamma_a, \gamma_b\} = \delta_{ab}, \quad \gamma_a^2 = \gamma_b^2 = 1, \quad (16)$$

whereas genuine fermions satisfy

$$\{c_a, c_b^\dagger\} = \delta_{ab}, \quad \{c_a, c_b\} = 0, \quad c_a^2 = 0. \quad (17)$$

Pairs of Majorana fermions (γ_A and γ_B) can be combined to form genuine fermions which can form a single 2 level system, depending on whether the fermion state is occupied or unoccupied. The next step is to consider what happens when we have $2N$ Majorana fermions. We can pair them up to make N ordinary fermions-

$$q_x = \frac{1}{2}(\gamma_{A,x} + i\gamma_{B,x}), \quad q_x^\dagger = \frac{1}{2}(\gamma_{A,x} - i\gamma_{B,x}) \quad (18)$$

(the same equations used to split the fermions into Majorana modes given in Eq. 15) with the number operators at each site x given as $N_x = q_x^\dagger q_x = 0, 1$. This gives a 2^N dimensional Fock space.

Why is it interesting to rewrite fermions in terms of pairs of Majorana fermions? Naively, this seems to be something which can always be done, and does not lead to anything new. But if a pair of Majoranas can be spatially separated, then the fermion made from them is delocalized. It is hence, protected from local changes that affect only one of them and hence protected from decoherence. This is why Majorana modes are expected to be relevant in quantum computation.

Now, let us get back to the Kitaev model. Let us first rewrite the Hamiltonian in terms of the Majorana operators to get

$$H = -\frac{\mu}{2} \sum_N (1 - i\gamma_{B,x}\gamma_{A,x}) + \sum_{N-1}^{x=1} \left[\frac{t}{2} (\gamma_{B,x}\gamma_{A,x+1} - \gamma_{A,x}\gamma_{B,x+1}) + i\frac{\Delta}{2} (\gamma_{A,x}\gamma_{B,x+1} + \gamma_{B,x}\gamma_{A,x+1}) \right] \quad (19)$$

To understand the physics in a simple way, let us now consider two simple limits, where the Hamiltonian becomes particularly simple. First, consider the case when $\mu = 0$ and $t = \Delta$. Here, we get

$$H = -it \sum_{x=1}^{N-1} \gamma_{B,x}\gamma_{A,x+1} \quad (20)$$

In the other limit, we take $\mu < 0$ and $t = \Delta = 0$ and get

$$H = -\frac{\mu}{2} \sum_{x=1}^N (1 - i\gamma_{B,x}\gamma_{A,x}) \quad (21)$$

What do these two limits mean?

We first analyze the second case. Here, the fermion at each site is simply broken up into two Majorana fermions and the μ term simply couples them as shown in Fig. 15. In this case, there is a unique ground state corresponding to the vacuum state with no fermions. Adding a fermion to the system costs an energy μ , so the system is gapped.

The first limit, on the other hand, couples Majorana modes at adjacent sites. In terms of new fermions $d_x = (\gamma_{B,x} + i\gamma_{A,x+1})/2$, the Hamiltonian can be rewritten as

$$H = 2t \sum_{N-1}^{x=1} d_x^\dagger d_x \quad (22)$$

This clearly shows that the system has a gap and the cost of adding a fermion to the system is $2t$. But the interesting point to note is that the Hamiltonian is completely independent of the two Majorana modes $\gamma_{A,1}$ and $\gamma_{B,N}$ as shown in Fig. 16, at the two ends of the wire. These two Majorana modes can be combined to form a fermion as

$$c_M = \frac{1}{2}(\gamma_{A,1} + i\gamma_{B,N}) \quad (23)$$

But this is a highly non-local fermion, since $\gamma_{A,1}$ and $\gamma_{B,N}$ are localized at opposite ends of the chain. Moreover, since this fermion is absent from the Hamiltonian, the energy is the same whether or not this fermion state is occupied. So the ground state is degenerate. If $|0\rangle$ is the ground state, then $c_M^\dagger |0\rangle$ is also a ground state. Note that $\gamma_a^2 = 1$ implies that there is no Pauli principle for the

Fig. 15 Here, the bonds are between Majorana modes at the same site. The ground state is unique and the end Majorana modes do not play any special role.

Fig. 16 Here, the bonds are between Majorana modes on adjacent sites. There are unpaired Majorana modes at the two ends. The ground state is doubly degenerate depending on whether the fermion state formed from the unpaired Majorana modes is occupied or unoccupied.

Majorana modes - in fact, as we saw earlier, there is no notion of occupation number for a single Majorana mode. Number operators only exist for fermions formed from pairs of Majorana modes. Depending on the occupation or not of the zero energy mode of the fermion - i.e., of C_M - there exists an odd or even number of fermions in the ground state referred to as 'fermion parity'. To change the parity, electrons have to be added or removed from the superconductor. This is unlike normal gapped superconductors, (e.g. the second limit), which have a unique ground state with even fermion parity.

In the more general case (Leijnse and Flensberg, 2012), when μ , t and Δ are non-zero, the general features of the topologically trivial case with a unique ground state, and the topologically non-trivial case with the Majorana edge states persist. Why do we call them topologically trivial and non trivial in the two cases? Well, in the trivial case there are no edge states and in the non-trivial case, there are edge states. In terms of the bulk properties of the Kitaev chain, one can find the bulk quasiparticle spectrum by going to momentum space (since the system is translationally invariant) and rewriting the Hamiltonian in Eq. (14) as

$$H = \sum_{k \in BZ} \zeta_k c_k^\dagger c_k + \sum_{k \in BZ} \left(e^{ik} c_k^\dagger c_{-k}^\dagger + e^{-ik} c_k c_{-k} \right) \quad (24)$$

$$= \sum_{k=0}^{\pi} \zeta_k \left(c_k^\dagger c_k + c_{-k}^\dagger c_{-k} \right) + \sum_{\pi}^{k=0} \left(\Delta_k c_k^\dagger c_{-k}^\dagger + \Delta_k^* c_{-k} c_k \right) \quad (25)$$

using $c_x = \frac{1}{\sqrt{N}} \sum_k e^{ikx} c_k$ and $c_x = c_{x+N}$, $\zeta_k = -2t \cos k - \mu$ and $\Delta_k = 2i\Delta \sin k$. This can be rewritten as

$$H = \sum_{k=0}^{\pi} \begin{pmatrix} c_k^\dagger & c_{-k} \end{pmatrix} \begin{pmatrix} \zeta_k & \Delta_k^* \\ \Delta_k & -\zeta_k \end{pmatrix} \begin{pmatrix} c_k \\ c_{-k}^\dagger \end{pmatrix} \quad (26)$$

We then introduce the Bogoliubov-de Gennes quasiparticles $\eta_k = \cos \frac{\theta_k}{2} c_k + i \sin \frac{\theta_k}{2} c_{-k}^\dagger$ with $\cos \theta_k = (-\mu - 2t \cos k)/E_k$ and $\sin \theta_k = 2\Delta \sin k/E_k$ to obtain

$$H = \sum_{k \in BZ} E_k \eta_k^\dagger \eta_k \quad (27)$$

with $E_k = \sqrt{(\zeta_k^2 + 4\Delta^2 \sin^2 k)}$.

Hence, the model is gapped, except when $\mu = -2t$ when $k = k_F = 0$ or when $\mu = +2t$ when $k = k_F = \pm \pi$. The lines $\mu = \pm 2t$ are where the system becomes gapless. For $\mu < 2t$, the system is topological and is adiabatically connected to the first limit with Majorana edge states. For $\mu > 2t$, the system is topologically trivial and is adiabatically connected to the second limit with no edge states. How do we see this? At first sight, it looks like both sides of the band-closing point at $\mu = 2t$ are identical. However, if we compute the bulk topological invariant, (which is beyond the scope of this article), for the system without boundaries (i.e., with periodic boundary conditions), and then cut the system to see what happens at the boundaries, then for $\mu = 2t$, we will find that the topological invariant has a certain value and no edge states when it is cut. On the other hand, when $\mu < 2t$, we will find that the topological invariant has a different value and that there are zero energy edge states when the system is cut. This shows us that there is a bulk topological invariant which distinguishes between topologically trivial and topologically non-trivial ground states. This analysis, in fact, also shows that there exists a bulk-boundary correspondence.

Statistics of the Majorana modes

Now, let us consider the statistics (Ivanov, 2001) of the Majorana modes. Let us start with the simplest case where $N = 1$. In this case, there are only two Majorana modes and the braid group only has a single generator τ . As we saw in the first section, τ is the operator that exchanges the Majorana modes A and B (as shown in Fig. 17)

$$\gamma_A \rightarrow \gamma'_A = \tau^\dagger \gamma_A \tau = e^{i\phi} \gamma_B, \quad (28)$$

but it does not fix the phase ϕ which is arbitrary. We can choose it to be $+1$. But then the phase of

$$\gamma_B \rightarrow \gamma'_B = \tau^\dagger \gamma_B \tau = e^{i\phi} \gamma_A \quad (29)$$

is forced to be -1 . This is because when there are only 2 Majorana modes, and the system is isolated, the fermion parity is forced to be conserved. The fermion state formed from the two Majorana modes is either occupied or unoccupied and we can check that

$$i\gamma_A \gamma_B = (1 - 2c_M^\dagger c_M) \quad (30)$$

So if the right hand side remains unchanged, then $i\gamma_A \gamma_B$ has to remain unchanged, which is only possible, if we choose the phases as shown above, since $\gamma_A \gamma_B = -\gamma_B \gamma_A$. Here, we can choose the exchange operator to be of the form

$$\tau = \frac{1}{\sqrt{2}} (1 + \gamma_A \gamma_B) \quad (31)$$

It is easy to check that τ defined this way is unitary and that it actually carries out the exchange by substituting for τ in Eq. (29). It is also easy to check that τ can be rewritten as $\exp(\pi \gamma_A \gamma_B / 4)$. If we write it in terms of the fermion number operator,

Fig. 17 Here, we exchange the Majorana modes belonging to the same fermion. This only gives rise to a phase and hence abelian statistics.

$$\tau = e^{i\pi(1-2n)/4}, \text{ where } n = c_M^\dagger c_M \quad (32)$$

Clearly, since n does not change, the statistics parameter is abelian and it cannot rotate states in the ground state manifold ($|0\rangle, c_M^\dagger|0\rangle$).

Now, let us see what happens when $N = 2$. Here, we have 4 Majorana modes $\gamma_i, i = A \dots D$ which can form 2 normal fermions

$$\begin{aligned} c_1 &= \frac{1}{2}(\gamma_A + i\gamma_B), \quad c_1^\dagger = \frac{1}{2}(\gamma_A - i\gamma_B) \\ c_2 &= \frac{1}{2}(\gamma_C + i\gamma_D), \quad c_2^\dagger = \frac{1}{2}(\gamma_C - i\gamma_D) \end{aligned} \quad (33)$$

The degenerate states of the system are given by $|n_1, n_2\rangle = c_1^\dagger c_2^\dagger |0, 0\rangle = \{|0, 0\rangle, |1, 0\rangle, |0, 1\rangle, |1, 1\rangle\}$. Operator τ_{AB} exchanges the Majoranas γ_A and γ_B keeping γ_C, γ_D unchanged and operator τ_{CD} exchanges the Majoranas γ_C and γ_D keeping γ_A, γ_B unchanged. Similarly, we can define, τ_{AC}, τ_{BD} , etc.

It is now clear that analogous to the $N = 1$ case, if we exchange the two Majorana zero modes from the same fermion, as shown in Fig. 17, we will only get a phase - i.e.,

$$\begin{aligned} \tau_{AB} |n_1, n_2\rangle &= e^{i\pi(1-2n_1)/4} |n_1, n_2\rangle \\ \tau_{CD} |n_1, n_2\rangle &= e^{i\pi(1-2n_2)/4} |n_1, n_2\rangle. \end{aligned} \quad (34)$$

In the first equation, n_2 comes along for a ride and in the second equation, n_1 comes along for a ride. So both these operators are abelian operators. But now, let us exchange one Majorana from one of the fermions with another Majorana from the other fermion, (as shown in Fig. 18)

$$\tau_{BC} = \frac{1}{\sqrt{2}}(1 + \gamma_B \gamma_C). \quad (35)$$

In terms of the fermions c_1 and c_2 , this can be written as

$$\tau_{BC} = \frac{1}{\sqrt{2}} \left[1 - i(c_1 - c_1^\dagger)(c_2 + c_2^\dagger) \right]. \quad (36)$$

Now acting this on $|n_1, n_2\rangle$ does not lead to a phase. Instead, it leads to a rotation in the space of degenerate states given by

$$\tau_{BC} |n_1, n_2\rangle = \frac{1}{\sqrt{2}} [|n_1, n_2\rangle + i(-1)^{n_1} |1 - n_1, 1 - n_2\rangle]. \quad (37)$$

If we now consider sequential exchanges, it is clear that different exchanges will not commute with one another - the final state will depend on the order of the operations. This is what is meant by saying that the Majorana particles have non-abelian statistics under exchange.

The derivation of the non-abelian statistics is not dependent on the details of how the exchange between the particles is carried out, and hence it cannot be changed by disorder or local details. It is topologically stable.

To understand multiple non-abelian anyons, as we already mentioned, we need to understand fusion paths, since the fusion rules do not lead to unique results. These fusion paths represent a basis of the degenerate ground state manifold, and are most conveniently studied in terms of conformal blocks of the appropriate conformal field theory. But that is beyond the scope of this article and we will stop here.

Fig. 18 Here, we exchange the Majorana modes belonging to two different fermions. This leads to a unitary rotation in the space of degenerate states and hence, to non-abelian statistics.

Conclusion

In this chapter, we have essentially given a detailed introduction to the idea of quantum statistics and how, in general, the wave-function of a many-particle system can pick up not only phases under exchanges of pairs of particles, but can also be rotated in a degenerate space, under exchange. More specifically, we have shown that abelian anyons transform as one-dimensional representations, and non-abelian anyons transform as higher dimensional representations of the braid group. We have introduced the concept of fusing or bringing together anyons to form new kinds of anyons. We have also discussed Kitaev's one-dimensional model of spinless fermions with nearest neighbor hopping as well as p -wave pairing to obtain end Majorana modes and have shown how the Majorana modes get rotated in the ground state manifold under exchange, as a specific example of non-abelian anyons.

The field of anyons, particularly, non-abelian anyons is still in its infancy. Majoranas are the simplest example of non-abelian anyons, and there has been a concerted effort all over the world to find them experimentally. Moreover, there has also been considerable amount of work, both in the theoretical and experimental arena to extend the work to more complex non-abelian anyons like Z_N parafermions (generalizations of the Majoranas which are also called Ising anyons, or Z_2 anyons) and Fibonacci anyons. The field is at the cross-roads of condensed matter physics and quantum information, and is expected not only to be of interest to researchers in both areas, but also benefit from the cross-fertilization of ideas from both fields.

Abstract

In general, the term anyons is applied to describe quasiparticles that display behavior that falls on a continuum between that of bosons and fermions. Two primary constructions of anyons exist: generalized exclusion statistics (GES), which extends the Pauli exclusion principle to allow a continuum of state occupancy, and fractional exchange statistics (FES), which generalizes the phase picked up by the wave function under particle exchange. In this chapter, we outline an alternative framework for simulating anyonic behavior called statistical anyons. Under this framework, anyonic features emerge from the average behavior of a statistical mixture of bosons and fermions. We demonstrate that statistical anyons are equivalent to GES anyons and can replicate the thermodynamic behavior of FES anyons.

Key points

- In the statistical anyon framework, the averaged behavior of an ensemble of bosons and fermions is used to simulate anyonic properties.
- Ideal statistical anyons are equivalent to interacting particles obeying Haldane’s generalized exclusion statistics, but do not replicate the topological exchange behavior of anyons obeying fractional exchange statistics.
- Statistical anyons can replicate the thermodynamic behavior of fractional exchange statistics anyons through a parameter-dependent choice of the fraction of the ensemble that are bosons.

Introduction

A primary distinguishing feature of quantum particles, in comparison to classical descriptions, is that they are truly indistinguishable. This indistinguishability does not arise from insufficient measurement precision, but rather is a fundamental property of the particles themselves. Quantum mechanics, as a linear theory, presents us with a method of accounting for this indistinguishability. The quantum state of a system of indistinguishable particles must be expressed as a superposition of all possible permutations of the individual particle states. However, such a composition is not unique. A family of possible solutions exists, with each solution distinguished by the phase picked up when two of the constituent particles are exchanged. In three spatial dimensions, the constraint that two sequential exchanges must leave the wave function unchanged leaves only two possibilities for this phase factor: positive and negative one. Particles with a wave function that is symmetric under exchange, corresponding to a phase factor of +1, are bosons, while particles with a wave function that is antisymmetric under exchange, corresponding to a phase factor of −1, are fermions.

Rather than being purely a concern of mathematical record keeping, this wave function symmetry has profound physical consequences. The antisymmetry of fermionic wave functions leads to vanishing probability that any two fermions will be found in the same quantum state (the Pauli exclusion principle), while no such restriction exists for bosons. Furthermore, a straightforward

examination of the average separation distance between a pair of indistinguishable particles shows that bosons are more likely to be found closer together while fermions are more likely to be found farther apart, in comparison to classical, distinguishable particles. This phenomenon, commonly called exchange forces, leads to an effective attraction between bosons and an effective repulsion between fermions.

While in three dimensions topological considerations limit the phase factor picked up under particle exchange to positive and negative one, this restriction does not apply in two-dimensional systems, as first demonstrated by Leinaas and Myrheim (1977). In 2D, there can exist a continuum of fractional statistics solutions, represented by a general phase factor of $e^{i\pi\nu}$ picked up under particle exchange (braiding). For $\nu = 2n$, where $n = 0, 1, 2, \dots$, bosonic behavior is recovered, while for $\nu = 2n + 1$, fermionic behavior is recovered. Shortly thereafter, Wilczek proposed that these anyons could exist as composite particles formed from a charged particle orbiting a tube of magnetic flux (Wilczek, 1982). Under this implementation particle exchange is accomplished by successive half-rotations of each quasiparticle around the other with the anyonic phase resulting from the Aharonov–Bohm effect. It was later proven by Arovas, Schrieffer, and Wilczek that quasiparticles entering the fractional quantum Hall regime also obey fractional exchange statistics (Arovas et al., 1984).

Anyons have been the subject of much recent interest due to the potential for non-Abelian anyons (Moore and Read, 1991) to serve as the basis of fault-tolerant topological quantum computers (Kitaev, 2003; Nayak et al., 2008). The non-Abelian nature of the braid group can be used to implement sequences of braids in multianyon systems that result in unitary transformations on the system state, analogous to quantum logic gates. As small, local perturbations do not change the braiding properties of the anyons, this method of quantum computation is, in principle, very robust against noise (Kitaev, 2003). While non-Abelian anyons have been the focus of much theoretical study, experimental detection remains a challenge and so far only indirect evidence of non-Abelian anyonic states has been found (Clarke et al., 2013; Kasahara et al., 2018; Banerjee et al., 2018).

As previously noted, the concept of fractional exchange statistics is only valid under the restriction to two dimensions. Thus, extending the concept of anyons to arbitrary dimensions requires a different approach. A dimension independent formulation of anyons is provided through the concept of *generalized exclusion statistics* (GES), first introduced by Haldane (1991). Based on a generalization of the Pauli exclusion principle, under GES particle nature is quantified by a statistical interaction that determines the degree to which two identical particles can occupy the same state. In practice, bosons or fermions subject to particular interparticle interactions can be treated as noninteracting particles obeying GES. Two well-studied interactions that can manifest GES are the inverse square law interaction of the Calogero–Sutherland (CS) model gas (Calogero, 1969; Sutherland, 1988; Murthy and Shankar, 1994b; Dasnières de Veigy and Ouvry, 1995; Bytsko and Fring, 1998; Meljanac et al., 2004; Comtet et al., 2007; del Campo, 2016) and the contact interactions of the 1D Lieb–Liniger model gas (Lieb and Liniger, 1963), with the distinctions that the statistical interaction occurs between particles of different momenta (Bernard and Wu, 1994; Isakov et al., 1996; Aneziris et al., 1991; Batchelor and Guan, 2007) and that the coupling constant of the interaction cannot be directly identified with the parameter controlling the statistics, except in the bosonic and fermionic limits (Ouvry and Polychronakos, 2009).

Despite the differences between their approaches, with FES generalizing the exchange behavior and GES generalizing the state occupancy of the exclusion principle, the two concepts of anyons are conceptually linked. When first proposing GES, Haldane noted that FES anyons confined to the lowest Landau level can be identified as obeying GES (Haldane, 1991). The two approaches can be combined, and it has been demonstrated that dimensionally confined, interacting FES anyons can be mapped to ideal FES anyons that obey GES (Kundu, 1999; Batchelor et al., 2006; Batchelor and Guan, 2006; Batchelor et al., 2007; Calabrese and Mintchev, 2007; Păţu et al., 2007; Batchelor et al., 2008; Hao et al., 2008; del Campo, 2008; Păţu et al., 2008a, b; Santachiara and Calabrese, 2008).

The differences in statistical behavior between bosons and fermions provide the foundation of quantum statistical mechanics. With this being the case, it is not surprising that much attention has been paid to studying the statistical mechanics of both FES and GES anyons. For GES anyons, much of this work has focused on analyzing the distribution function (Wu, 1994; Isakov, 1994b; Khare, 2005; Rovenchak, 2014; Joyce et al., 1996; Anghel, 2013), partition functions (Murthy and Shankar, 1994b; Dasnières de Veigy and Ouvry, 1995; Comtet et al., 2007; Ouvry and Polychronakos, 2021), virial coefficients (Murthy and Shankar, 1994a; Isakov et al., 1996; Rovenchak, 2014), equation of state (Wu, 1994; Dasnières de Veigy and Ouvry, 1995; Isakov et al., 1996; Ouvry and Polychronakos, 2021), and deriving thermodynamic behavior using the thermodynamic Bethe ansatz (Bernard and Wu, 1994; Isakov, 1994a, b; Guan and Chen, 2016). Similarly, the partition function (Bhaduri et al., 1991; Myrheim, 1999) and the virial coefficients (Arovas et al., 1985; Sen, 1992; Sporre et al., 1993; Giacconi et al., 1996; Lerda, 1992; Myrheim, 1999; Polychronakos, 2000; Khare, 2005) for FES anyons have been studied, along with their relativistic thermodynamics (Chen, 1995) and phase transitions (Nasu and Motome, 2015).

Despite significant theoretical analysis, the difficulty of accessing anyons had led to comparatively fewer experimental studies. A typical approach to detecting FES anyons arising in the fractional quantum Hall regime is through the use of quasiparticle interferometers whose interference effects are sensitive to the anyonic phase (de Chamon et al., 1997; Ji et al., 2003; Law et al., 2006; Bonderson et al., 2006). This method has seen experimental implementation (Camino et al., 2005; Ofek et al., 2010; McClure et al., 2012; Willett et al., 2013; Nakamura et al., 2019; Willett et al., 2019); however distinguishing signatures of the anyonic phase from interference effects arising from Coulomb blockading and Aharonov–Bohm interference makes this approach challenging (Bartolomei et al., 2020).

In this chapter we detail an alternative framework for anyons, in which the anyonic behavior arises from a statistical mixture of boson and fermion pairs. This approach is referred to as “statistical anyons” (Myers and Deffner, 2021). In Section “Statistical”

“anyons” we motivate the main idea behind statistical anyons using the Hong-Ou-Mandel (HOM) effect first observed in photonic interferometry (Hong et al., 1987). Then in Section “Equilibrium thermodynamics of statistical anyons” we demonstrate how the statistical anyon framework is equivalent to the GES formulation of anyons. In Section “Thermodynamic equivalence” we examine the equilibrium thermodynamic properties of statistical anyons in comparison to FES anyons. We show that, with a parameter-dependent choice of the anyonic phase, statistical anyons can mimic the thermodynamics of FES anyons. Finally, in Section “Conclusion” we conclude with a summary and perspective on future research directions.

“Statistical” anyons

To motivate the main concept behind statistical anyons, we begin with a brief overview of the typical HOM effect. Consider a pair of entangled photons incident symmetrically on a two-port 50/50 beamsplitter. The initial bosonic spatial state is described by a symmetric superposition of each input,

$$|\psi_i^B\rangle = \frac{1}{\sqrt{2}}(|a\rangle_1|b\rangle_2 + |b\rangle_1|a\rangle_2). \quad (1)$$

The operation of the beamsplitter evolves state $|a\rangle \rightarrow \frac{1}{\sqrt{2}}(|c\rangle + i|d\rangle)$ and state $|b\rangle \rightarrow \frac{1}{\sqrt{2}}(i|c\rangle + |d\rangle)$ with the imaginary component denoting the phase shift of π picked up upon reflection. The final state after the beamsplitter is then

$$|\psi_f^B\rangle = \frac{i}{\sqrt{2}}(|c\rangle_1|c\rangle_2 + |d\rangle_1|d\rangle_2). \quad (2)$$

Remarkably, we see that the only possible output states are those in which both photons exit the same port of the beamsplitter. This “boson bunching” can be interpreted as a consequence of the effective attraction between bosons arising from the exchange forces (Hong et al., 1987).

It is important to note that the above analysis assumes that all other degrees of freedom of the photons (such as frequency and polarization) are identical. However, it is straightforward to extend the HOM analysis to the case in which this is no longer the case (Zeilinger, 1998). Consider a case in which the incident photons are prepared in one of the maximally entangled Bell states in the polarization basis. The four possible Bell pairs are

$$\begin{aligned} |\Phi_A\rangle &= \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle), \\ |\Phi_B\rangle &= \frac{1}{\sqrt{2}}(|00\rangle - |11\rangle), \\ |\Phi_C\rangle &= \frac{1}{\sqrt{2}}(|01\rangle + |10\rangle), \\ |\Phi_D\rangle &= \frac{1}{\sqrt{2}}(|01\rangle - |10\rangle), \end{aligned} \quad (3)$$

where $|0\rangle$ and $|1\rangle$ denote orthogonal polarization states. Three of these states are symmetric under exchange ($|\Phi_A\rangle$, $|\Phi_B\rangle$, and $|\Phi_C\rangle$) while one of them ($|\Phi_D\rangle$) is antisymmetric. Since photons are bosons, their overall wave function must still be symmetric. This can be accomplished by either pairing a symmetric spatial state with one of the three symmetric polarization states, or by pairing an antisymmetric spatial state with the antisymmetric polarization state. For the latter case, the overall wave function for the incident photon pair is,

$$|\Psi_i^F\rangle = \frac{1}{\sqrt{2}}(|a\rangle_1|b\rangle_2 - |b\rangle_1|a\rangle_2) \otimes |\Phi_D\rangle. \quad (4)$$

Assuming it is nonpolarizing, the beamsplitter acts only on the spatial portion of the wavefunction resulting in the output state

$$|\psi_f^F\rangle = \frac{1}{\sqrt{2}}(|c\rangle_1|d\rangle_2 - |d\rangle_1|c\rangle_2). \quad (5)$$

We see that now, unlike the previous case, the only possible output states are those in which both photons exit opposite ports of the beamsplitter. Despite the fact that photons are fundamentally bosons, since the beamsplitter only acts on the antisymmetric portion of the overall state, the photons behave like fermions. This guarantee that the photons exit opposite ports of the beamsplitter can be seen as a manifestation of the Pauli exclusion principle. In Fig. 1A we illustrate the outcomes for both the spatially symmetric and antisymmetric initial states.

In a sense, the additional degree of freedom provided by the polarization can be thought of as a quantum substrate on which the desired statistics can be constructed. Notably, both bunching and antibunching behaviors vanish if the photons become distinguishable. A simple means of accomplishing this is to introduce a difference in the flight time between the two ports of the beamsplitter (Zeilinger, 1998).

Fig. 1 (A) Possible transmission and reflection combinations for two photons incident on a two-port 50/50 beamsplitter. For photon pairs with symmetric (bosonic) spatial states possibilities (i) and (iv) interfere destructively while for photons with antisymmetric (fermionic) spatial states (i) and (iv) interfere constructively. (B) Example of statistical anyons for $N = 5$ photon pairs. Top figure: The particle pairs are incident on opposite ports of the beamsplitter. *Blue particles* represent pairs with symmetric entanglement and *red particles* pairs with antisymmetric entanglement. At the output, the *blue pairs* always exit at the same port, and the *red pairs* at opposite ports. Bottom figure: The statistical anyonic representation of the same process. Here particle size represents the normalized probability density of finding a particle at that port.

The HOM bunching and antibunching can be extended to anyonic statistics through the introduction of a phase that tunes between the symmetric and antisymmetric Bell states. This phase can be introduced in a number of ways, including using a rotated polarization beamsplitter (Matthews et al., 2013), adjusting path length (Rarity et al., 1990; Michler et al., 1996), or introducing phase plates (Wang et al., 2007). In the statistical anyon framework, this phase is effectively introduced by averaging over the behavior of a statistical mixture of symmetrically and antisymmetrically entangled photon pairs. Consider an incident anyonic wave function of the form

$$|\psi_i^A\rangle = \frac{1}{\sqrt{2}}(|a\rangle_1|b\rangle_2 + e^{i\pi\nu}|b\rangle_1|a\rangle_2). \quad (6)$$

After the beamsplitter, the probability of finding both photons in the same output port is

$$P_{\text{same}} = \frac{1}{2}(1 + \cos[\pi\nu]). \quad (7)$$

By varying ν , we see that the probability of finding both photons at the same port can be tuned between the bosonic and fermionic limits of 1 and 0, respectively. Now let us consider the case of N photon pairs incident on the beam splitter, of which some fraction are symmetrically entangled and the rest are antisymmetrically entangled. We can replicate the same probability of finding both photons of a pair at the same port *on average* by varying the ratio of symmetrically to antisymmetrically entangled pairs in the ensemble. In this framework the anyonic phase parameter ν is associated with the probability that any given pair in the mixture is symmetrically entangled, $\nu = \nu(p_B)$. This behavior is shown pictorial in Fig. 1B.

We refer to this implementation as “statistical anyons” in contrast to FES anyons and GES anyons. Each formulation of anyons displays behavior interpolating between that of fermions and bosons. However, in the statistical anyon framework this behavior is a result of averaging over a large number of particles, while for FES anyons it is a property of the quasiparticles themselves and for GES anyons it is a product of the interparticle interactions.

Topologically, statistical anyons are akin to GES anyons and distinct from FES anyons. The two-dimensional nature of FES anyons means that two repeated exchanges is a topologically distinct from doing nothing and does not necessarily result in an unchanged wave function (Leinaas and Myrheim, 1977; Lerda, 1992). Since the configuration space of FES anyons is represented by the braid group, the *direction* of the exchange is significant. Two exchanges in the same direction will result in a wavefunction different from the original by a phase of $e^{2i\pi\nu}$. Like GES anyons, two repeated exchanges of statistical anyons will always return the original wave function, since each element of the statistical anyon ensemble is fundamentally a boson or fermion. For statistical anyons the anyonic phase is an average over the bosonic and fermionic phases of the constituent particles and thus will always fall between negative one and one. Thus the statistical anyon mixture corresponding to a FES anyon phase of $e^{i\pi\nu}$ will be weighted such

Fig. 2 (A) Comparison between the exchange phase of FES and statistical anyons. For FES anyons, the direction of the exchange determines the sign of the anyonic phase parameter ν . Thus the space of possible FES anyonic phases can be represented by a unit circle in the complex plane with the bosonic and fermionic phases lying on the intercepts with the real axis at ± 1 . For statistical anyons, the anyonic phase parameter is given by the probability that a given pair of particles in the ensemble will be bosons. As such, the space of possible statistical anyon phases is confined to the real axis between positive and negative one. This leads to reduced complexity, as the sign of the phase (direction of exchange) is irrelevant. (B) Comparison between 2D FES and statistical anyons undergoing two exchanges. For FES anyons two exchanges in opposite directions leaves the wavefunction unchanged (left diagram), while two exchanges in the same direction results in the original wavefunction with a phase of $e^{2i\pi\nu}$ (middle diagram). For statistical anyons the direction of the exchange is irrelevant, with two exchanges always resulting in an unchanged wavefunction (right diagram).

that the average phase of the mixture is $\cos[\pi\nu]$. Note that the since the direction of exchange is irrelevant for statistical anyons, the FES anyonic phases of $e^{i\pi\nu}$ and $e^{-i\pi\nu}$ are both identified with the same statistical anyon phase. These differences between the FES and statistical anyon phases are illustrated graphically in Fig. 2.

Statistical anyon wavefunction

Let us now consider how to treat statistical anyons outside of the framework of quantum optics. In general, the symmetric spatial wave function for a pair of bosons is

$$\Psi_B(\mathbf{x}) = \frac{1}{\sqrt{2(1 + \delta_{n_1, n_2})}} [\psi_{n_1}(x)\psi_{n_2}(y) + \psi_{n_1}(y)\psi_{n_2}(x)], \quad (8)$$

where $\psi_n(x)$ is the normalized single-particle eigenstate corresponding to quantum number n . Note that the normalization coefficient for bosons depends on whether the particles occupy the same state. Conversely, the antisymmetric spatial wave function for a pair of fermions is

$$\Psi_F(\mathbf{x}) = \frac{1}{\sqrt{2}} [\psi_{n_1}(x)\psi_{n_2}(y) - \psi_{n_1}(y)\psi_{n_2}(x)]. \quad (9)$$

In this case no delta function is required in the normalization, as the fermionic wave function vanishes if both fermions ever occupy the same state.

Now we consider a case in which we have N independent pairs of particles, of which N_B are bosons and $N_F = N - N_B$ are fermions. The total wave function is then

$$\Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) = \prod_{j=1}^{N_B} \Psi_B(\mathbf{x}_j) \prod_{k=N_B+1}^N \Psi_F(\mathbf{x}_k), \quad (10)$$

where $\mathbf{x} = (x, y)$. This wave function can be equivalently represented in the framework of statistical anyons as

$$\Psi(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N) = \prod_{j=1}^N \Psi_A(\mathbf{x}_j), \quad (11)$$

where

$$\Psi_A(\mathbf{x}_j) = \frac{1}{\sqrt{2(1 + \delta_{n_1, n_2})}} [\psi_{n_1}(x_j)\psi_{n_2}(y_j) + e^{i\pi\nu_j}\psi_{n_1}(y_j)\psi_{n_2}(x_j)]. \quad (12)$$

We note here a significant difference between the statistical anyon wave function in Eq. (11) and the wave function for FES anyons. From Eqs. (11) and (12), it is clear that the statistical anyon wave function can always be constructed from a product of superpositions of the single particle wave functions. This is *not* generally true for the wave function of FES anyons, outside of the bosonic and fermionic limits (Lerda, 1992; Myrheim, 1999; Khare, 2005).

Since Eqs. (11) and (10) must match, we select the anyonic phase parameter in Eq. (12) to be $v_j = \Theta(j - N_B - 1)$, where $\Theta(\cdot)$ is the Heaviside step function, using the convention $\Theta(0) = 1$. This way, the anyonic factor in Eq. (12) gives the ‘average’ phase picked up under exchange for any one of the N pairs of particles. For a large ensemble of particles ($N \gg 1$), we can express the number of bosonic and fermionic particle pairs as $N_B = Np_B$ and $N_F = Np_F = N(1 - p_B)$ where p_B (p_F) is the probability of a particle pair having bosonic (fermionic) symmetry.

In the limit of a single two-particle system, the anyonic wave function becomes

$$\Psi_A(\mathbf{x}) = \frac{1}{\sqrt{2(1 + \delta_{n_1, n_2})}} [\psi_{n_1}(\mathbf{x})\psi_{n_2}(\mathbf{y}) \pm \psi_{n_1}(\mathbf{y})\psi_{n_2}(\mathbf{x})], \quad (13)$$

with the sign determined by whether p_B is zero or one. This is a reflection of the fact that each individual pair of particles in the ensemble is, in reality, either bosonic or fermionic.

Statistical anyons in the second quantization

To understand the how to extend the framework of statistical anyons to the second quantization we must determine the appropriate commutation relations. Let us first consider the case of FES anyons. The creation and annihilation operators for FES anyons can be determined from the bosonic or fermionic operators via the Jordan–Wigner transformation, and obey the following commutation relations (Lerda and Sciuto, 1993):

$$\begin{aligned} a(\mathbf{x}_C)a(\mathbf{y}_C) - e^{-i\pi v}a(\mathbf{y}_C)a(\mathbf{x}_C) &= 0, \\ a(\mathbf{x}_C)a^\dagger(\mathbf{y}_C) - e^{i\pi v}a^\dagger(\mathbf{y}_C)a(\mathbf{x}_C) &= 0, \\ a^\dagger(\mathbf{x}_C)a(\mathbf{y}_C) - e^{i\pi v}a(\mathbf{y}_C)a^\dagger(\mathbf{x}_C) &= 0, \\ a^\dagger(\mathbf{x}_C)a^\dagger(\mathbf{y}_C) - e^{-i\pi v}a^\dagger(\mathbf{y}_C)a^\dagger(\mathbf{x}_C) &= 0. \end{aligned} \quad (14)$$

The direction-dependent nature of the FES phase factor is incorporated through the dependence of the commutators on the curve $\mathcal{C}$, which indicates the direction of the exchange rotation. We see that taking the limit of $v \rightarrow 0$ and $v \rightarrow 1$ in Eq. (14) restores the bosonic commutation and fermionic anticommutation relations, respectively.

For particles at the same location ($\mathbf{x}_C = \mathbf{y}_C$), the canonical commutation relation reduces to (Lerda and Sciuto, 1993; Khare, 2005)

$$a(\mathbf{x}_C)a^\dagger(\mathbf{x}_C) \pm a^\dagger(\mathbf{x}_C)a(\mathbf{x}_C) = 1, \quad (15)$$

with the (+) occurring if the anyonic operators are constructed from transformed fermionic operators, and the (−) if they are constructed from transformed bosonic operators. An important feature of FES anyons is the fact that they obey an exclusion principle for all $v \neq 0$. As is the case for GES anyons, the anyonic phase parameter can be thought of as quantifying the degree of repulsion between two identical particles (Khare, 2005).

For the case of statistical anyons, we follow a similar approach to the construction of the statistical anyon wave function in the first quantization. Let us consider an N -particle Fock state, consisting of N_B bosons and $N_F = N - N_B$ fermions. This state can be constructed from the vacuum state by applying N_B bosonic and N_F fermionic creation operators

$$|1\rangle_1|1\rangle_2 \dots |1\rangle_N = \prod_{j=1}^{N_B} b_j^\dagger |0\rangle_j \prod_{k=N_B+1}^N f_k^\dagger |0\rangle_k. \quad (16)$$

We can construct an identical state by applying a statistical anyon creation operator to the vacuum state N times,

$$|1\rangle_1|1\rangle_2 \dots |1\rangle_N = \prod_{j=1}^N s_j^\dagger |0\rangle_j. \quad (17)$$

The statistical anyon creation operator, $s_j^\dagger$, must reduce to the bosonic creation operator for $j \leq N_B$ and to the fermionic creation operator for $j > N_B$. This condition allows us to construct the statistical anyon commutation relations,

$$\begin{aligned} s_j^\dagger s_j - e^{i\pi\Theta(j - N_B - 1)} s_j s_j^\dagger &= 1, \\ s_j s_j^\dagger - e^{i\pi\Theta(j - N_B - 1)} s_j^\dagger s_j &= 1, \\ s_j^\dagger s_j^\dagger - e^{i\pi\Theta(j - N_B - 1)} s_j^\dagger s_j^\dagger &= 0, \\ s_j s_j - e^{i\pi\Theta(j - N_B - 1)} s_j s_j &= 0. \end{aligned} \quad (18)$$

Note the similar form of the statistical anyon phase to the case of the statistical anyon phase in the first quantization wave function.

In the single-particle limit, the canonical commutation reduces to

$$s_j s_j^\dagger \pm s_j^\dagger s_j = 1, \quad (19)$$

as in reality the particle is either a boson or a fermion. This echoes Eq. (15), where the form of the commutation relation depends on whether the anyonic operators are constructed from transformed fermionic or bosonic operators.

Statistical anyons and generalized exclusion statistics

In the previous sections, we have outlined the framework of statistical anyons and repeatedly compared it to the case of FES anyons. In this section, we now compare statistical anyons to GES anyons.

Previously, we noted that, outside the bosonic limit, FES anyons obey the exclusion principle (Khare, 2005). Statistical anyons, on the other hand, only obey the exclusion principle in the fermionic limit. Outside of this limit, statistical anyons admit “partially occupied” states that arise from averaging over the occupancy of all N systems. This behavior is more akin to that of GES anyons.

GES is constructed by extending the Pauli exclusion principle through the definition of a parameterized differential relation that quantifies the change in the dimension of the Hilbert space of a discrete-state system upon a change in the particle number (Haldane, 1991)

$$\Delta d_{\text{GES}} = -g\Delta N. \quad (20)$$

Since infinitely many bosons can occupy the same state, for bosons the dimension is independent of the particle number, thus $g = 0$. As only a single fermion can occupy each state, the dimension scales directly with the total particle number, thus $g = 1$.

Physical systems known to host GES anyons include the CS model gas (Murthy and Shankar, 1994b; Bytsko and Fring, 1998; Meljanac et al., 2004; del Campo, 2016), which can also be mapped to FES anyons confined to the lowest Landau level (Wu, 1994; Dasnières de Veigy and Ouvry, 1994, 1995; Ouvry and Polychronakos, 2018; Ouvry, 2001; Ouvry and Polychronakos, 2021). Under this condition, the thermodynamic potential for a gas of particles with a discrete one-body spectrum obeying GES can be constructed from a generalization of the relation found for Calogero model GES anyons or lowest Landau level topological anyons (Ouvry and Polychronakos, 2021). GES can also manifest in Lieb–Liniger and hard core Tonks–Girardeau gasses with δ -function potentials (Kundu, 1999; Batchelor et al., 2006; Girardeau, 2006; Batchelor et al., 2007; Calabrese and Mintchev, 2007; Pâtu et al., 2007; Batchelor et al., 2008; Hao et al., 2008; del Campo, 2008; Pâtu et al., 2008a, b; Santachiara and Calabrese, 2008) as well as Hubbard chains (Vitoriano and Coutinho-Filho, 2009; Tang et al., 2015). The anyonic behavior of the latter can be simulated using ultracold gasses (Yannouleas and Landman, 2019). In general, GES can be connected with a class of integrable models solvable by the thermodynamic Bethe ansatz (Bernard and Wu, 1994; Isakov, 1994a, b; Bytsko and Fring, 1998; Guan and Chen, 2016).

We can follow a similar approach for statistical anyons. In this case the change in the Hilbert space dimension will be the weighted average over the change for bosons and fermions

$$\Delta d_{\text{SA}} = p_B \Delta d_B + p_F \Delta d_F. \quad (21)$$

Using $\Delta d_B = 0$ and $\Delta d_F = -\Delta N$ this simplifies to

$$\Delta d_{\text{SA}} = -p_F \Delta N. \quad (22)$$

We see here that Eq. (22) is equivalent to Eq. (20) with the statistical parameter, g , replaced by the fermion probability.

The fact that GES anyons could be described in terms of bosons and fermions was first noted by Murthy and Shankar (1994b) in the context of the CS model gas. They showed that partition function for the GES anyons could be factored into bosonic and fermionic components raised to the power of the GES parameter g and $g - 1$, respectively. Motivated by these results, we will explicitly demonstrate the equivalence of the statistical and GES anyon frameworks for the CS model.

The two-particle CS Hamiltonian is (Calogero, 1971)

$$H = \sum_{i=1}^2 \left(-\frac{\hbar^2}{2m} \frac{\partial^2}{\partial x_i^2} + \frac{1}{2} m \omega^2 x_i^2 \right) + \sum_{j < i}^2 \frac{\hbar^2 g(g-1)}{2m(x_i - x_j)^2}. \quad (23)$$

The wavefunction corresponding to this Hamiltonian can be written as (Polychronakos, 1989; Brink et al., 1992; Isakov, 1994a; Gurappa and Panigrahi, 1999)

$$\Psi(x_1, x_2) = (x_2 - x_1)^g \Phi^+(x_1, x_2) \quad (24)$$

where the $(x_2 - x_1)^g$ term is the two-particle simplification of the Jastrow product and $\Phi^+(x_1, x_2)$ is a completely symmetric wave function. For the case of $g = 0$ we restore the wavefunction of two bosons in a pure harmonic potential, and for $g = 1$ we restore the wavefunction of two fermions in a pure harmonic potential. Now consider a large ensemble of N identical systems of which $N_B = Np_B$ consist of bosons and $N_F = Np_F$ consist of fermions. The global wavefunction can then be expressed as

$$\Psi_N(x_1, x_2) = \prod_{i=1}^{N_B} \Psi_i^B(x_1, x_2) \prod_{j=N_B+1}^N \Psi_j^F(x_1, x_2). \quad (25)$$

Replacing $\Psi_i^B(x_1, x_2)$ and $\Psi_j^F(x_1, x_2)$ in Eq. (25) with the bosonic and fermionic limits of Eq. (24) we have

$$\begin{aligned} \Psi_N(x_1, x_2) &= \prod_{i=1}^{N_B} \Phi_i^+(x_1, x_2) \prod_{j=N_B+1}^N (x_2 - x_1)^{N_F} \Phi_j^+(x_1, x_2) \\ &= [\Phi^+(x_1, x_2)]^{N_B} [(x_2 - x_1) \Phi^+(x_1, x_2)]^{N_F}. \end{aligned} \quad (26)$$

Using $N_F + N_B = N$ and $N_F = Np_F$ this simplifies to

$$\Psi_N(x_1, x_2) = [(x_2 - x_1)^{p_F} \Phi^+(x_1, x_2)]^N. \quad (27)$$

Thus we see that Eq. (25) can be equivalently expressed as

$$\Psi_N(x_1, x_2) = \prod_{i=1}^N \Psi_i^A(x_1, x_2), \quad (28)$$

where $\Psi^A(x_1, x_2) = (x_2 - x_1)^{p_F} \Phi^+(x_1, x_2)$ can be considered the *average* wavefunction across all N systems. This is identical to (24) with g replaced by p_F .

Let us now consider the spectrum. It is well established that the Calogero model can be mapped to a system of noninteracting oscillators with a shifted energy via similarity or canonical transformations (Polychronakos, 1989; Brink et al., 1992; Brzeziński et al., 1999; Gurappa and Panigrahi, 1999, 2000; Polychronakos, 2006; Chen, 2018). In the relative and center of mass coordinate system, the eigenenergies corresponding to relative motion of (23) are (Brink et al., 1992; Brzeziński et al., 1999; Gurappa and Panigrahi, 1999; Polychronakos, 2006)

$$E_n = \hbar\omega \left(2n + g + \frac{1}{2} \right), \quad (29)$$

where $n = (0, 1, 2, \dots)$. Considering now a system of two noninteracting bosons or fermions in a harmonic potential. The eigenenergies corresponding to the relative coordinate are identical to those of the harmonic oscillator

$$E_{n_r} = \hbar\omega \left(n_r + \frac{1}{2} \right), \quad (30)$$

where the quantum symmetry is encoded in the fact that n_r consists of even integers for the case of bosons, and odd integers for the case of fermions. Using this we can rewrite (30) as

$$E_B = \hbar\omega \left(2n + \frac{1}{2} \right) \quad \text{and} \quad E_F = \hbar\omega \left(2n + 1 + \frac{1}{2} \right) \quad (31)$$

where now $n = (0, 1, 2, \dots)$. The spectrum of N identical systems, of which N_B are bosons and N_F are fermions, is then

$$E_N = N_B E_B + N_F E_F = N\hbar\omega \left[\left(2n + \frac{1}{2} \right) (p_B + p_F) + p_F \right] = N\hbar\omega \left(2n + p_F + \frac{1}{2} \right). \quad (32)$$

The *average* spectrum for the relative coordinate of any given pair of particles in the mixture is then

$$E_n = \hbar\omega \left(2n + p_F + \frac{1}{2} \right) \quad (33)$$

which is identical to Eq. (29).

In this section we have demonstrated explicitly that GES can be constructed from the average behavior of an ideal statistical mixture of bosons and fermions, and identified the GES parameter with the statistical weights of the mixture. We conclude the section with Table 1, which summarizes the important distinctions between the three anyon frameworks, FES, GES, and statistical anyons.

Equilibrium thermodynamics of statistical anyons

As a branch of physics, thermodynamics was expressly developed to study the average behavior of systems consisting of a large number of microscopic constituents. As the anyonic behavior of statistical anyons arises from averaging over the behavior of a large ensemble of bosons and fermions, the statistical anyon framework is particularly suited to the study of thermodynamic behavior. In this section we will derive the equilibrium thermodynamic quantities for one- and two-dimensional statistical anyons, and compare this behavior to FES anyons. Ultimately, we will demonstrate how a particular choice of the statistical anyon phase (determined by the statistical weights of the Bose–Fermi mixture) can be used to mimic the thermodynamic behavior of FES anyons.

Table 1 Comparison of FES, GES, and statistical anyons

	<i>Dim.</i>	<i>Rep. group</i>	<i>Exclusion principle</i>	<i>Origin of anyonic behavior</i>
FES	2D	Braid	Hard core for all $v \neq 0$	Complex phase introduced by exchange
GES	Arbitrary	Permutation	Generalized exclusion	Generalization of state occupancy arising from interparticle interactions
Statistical	Arbitrary	Permutation	Generalized exclusion	Statistical average of bosonic and fermionic behavior

1D Statistical anyons

The first step in determining equilibrium thermodynamic quantities, such as internal energy, entropy, and heat capacity, is deriving the appropriate partition function. Motivated by the manifestation of GES in trapped, interacting gasses, as well as the verification of statistical and GES anyon equivalence for the CS model given in the previous section, let us consider two statistical anyons in a 1D harmonic potential. However, unlike the CS model GES, we will consider *noninteracting* particles. There is particular precedent for studying trapped boson–fermion mixtures both theoretically (Fang et al., 2011; Dehkharghani et al., 2017; Decamp et al., 2017) and experimentally (Fukuhara et al., 2009; Onofrio, 2016; Sowiński and García-March, 2019). This work has focused primarily on effects on the ground state configurations that arise from interactions between the boson and fermion species. In the statistical anyon framework we instead consider the average collective behavior that arises in the ideal gas limit of such a mixture.

The Hamiltonian for two harmonically confined noninteracting statistical anyons is

$$H = \frac{p_1^2 + p_2^2}{2m} + \frac{1}{2}m\omega^2(x_1^2 + x_2^2). \quad (34)$$

For N independent pairs of particles, the partition function is given by

$$Z_A^N = \text{tr}\{e^{-\beta H}\} = \prod_{j=1}^N \int dx_j \int dy_j \langle x_j y_j | e^{-\beta H_j} | x_j y_j \rangle \quad (35)$$

Inserting the identity in the energy basis twice yields

$$Z_A^N = \prod_{j=1}^N \int dx_j \int dy_j \sum_{n_1^{(j)}, n_2^{(j)}=0}^{\infty} \sum_{m_1^{(j)}, m_2^{(j)}=0}^{\infty} \Psi_A^*(x_j, y_j) \Psi_A(x_j, y_j) \times e^{-\beta \hbar \omega (m_1^{(j)} + m_2^{(j)} + 1)} \langle n_1^{(j)} n_2^{(j)} | m_1^{(j)} m_2^{(j)} \rangle \quad (36)$$

where $\Psi_A(x_j, y_j)$ is given by Eq. (12) with

$$\psi_n(x) = \frac{1}{\sqrt{2^n n!}} \left(\frac{m\omega}{\pi \hbar} \right)^{1/4} e^{-\frac{m\omega x^2}{2\hbar}} H_n \left(\sqrt{\frac{m\omega}{\hbar}} x \right). \quad (37)$$

Evaluating the integral in Eq. (36) results in

$$Z_A^N = \prod_{j=1}^N \sum_{n_1^{(j)}, n_2^{(j)}=0}^{\infty} \frac{1}{4} e^{-\beta \hbar \omega (n_1^{(j)} + n_2^{(j)} + 1)} \left(2 + e^{-i\pi \Theta(j - N_B + 1)} \delta_{n_1^{(j)}, n_2^{(j)}} + e^{i\pi \Theta(j - N_B + 1)} \delta_{n_1^{(j)}, n_2^{(j)}} \right), \quad (38)$$

where δ_{n_1, n_2} is the Kronecker delta. The step functions in Eq. (38) can be evaluated by separating the product into two, one from 1 to N_B and a second from $N_B + 1$ to N

$$Z_A^N = \prod_{j=1}^{N_B} \sum_{n_1^{(j)}, n_2^{(j)}=0}^{\infty} \frac{1}{2} e^{-\beta \hbar \omega (n_1^{(j)} + n_2^{(j)} + 1)} \left(1 + \delta_{n_1^{(j)}, n_2^{(j)}} \right) \times \prod_{j=N_B+1}^N \sum_{n_1^{(j)}, n_2^{(j)}=0}^{\infty} \frac{1}{2} e^{-\beta \hbar \omega (n_1^{(j)} + n_2^{(j)} + 1)} \left(1 - \delta_{n_1^{(j)}, n_2^{(j)}} \right). \quad (39)$$

Eq. (39) can be rewritten in the simple form

$$Z_A^N = \prod_{j=1}^{N_B} Z_B^{(j)} \prod_{k=1}^{N_F} Z_F^{(k)} = Z_B^{N_B} Z_F^{N_F}, \quad (40)$$

where Z_B and Z_F are the individual partition functions for two bosons and two fermions in harmonic potential

$$\begin{aligned} Z_B &= \sum_{n_1, n_2=0}^{\infty} \frac{1}{2} (1 + \delta_{n_1, n_2}) e^{-\beta \hbar \omega (n_1 + n_2 + 1)} \\ Z_F &= \sum_{n_1, n_2=0}^{\infty} \frac{1}{2} (1 - \delta_{n_1, n_2}) e^{-\beta \hbar \omega (n_1 + n_2 + 1)}. \end{aligned} \quad (41)$$

Finally, using the fact that for large N we can express the number of bosonic and fermionic particle pairs as $N_B = N p_B$ and $N_F = N p_F = N(1 - p_B)$ where p_B (p_F) is the probability of a particle pair having bosonic (fermionic) symmetry, the statistical anyon partition function can be expressed as

$$Z_A^N = (Z_B^{p_B} Z_F^{p_F})^N. \quad (42)$$

Thus the partition function for a single pair of statistical anyons is

$$Z_{SA} = (Z_B)^{p_B} (Z_F)^{1-p_B}. \quad (43)$$

As expected, Eq. (43) is identical to that of a GES CS model gas (Murthy and Shankar, 1994b), with the GES parameter g replaced by $1 - p_B$. However, we see that in the statistical anyon framework the anyonic behavior arises purely out of the average properties, rather than from an interaction term in the Hamiltonian.

From Eq. (43) we can determine the internal energy, free energy, entropy, and heat capacity by taking the appropriate derivatives

$$\begin{aligned} E &= -\frac{\partial}{\partial \beta} \ln(Z_{\text{SA}}), & F &= -\frac{1}{\beta} \ln(Z_{\text{SA}}), \\ S &= k_B \beta^2 \frac{\partial F}{\partial \beta}, & C &= -k_B \beta^2 \frac{\partial E}{\partial \beta}, \end{aligned} \quad (44)$$

where β is the inverse temperature and k_B is Boltzmann's constant. For 1D ideal statistical anyons in a harmonic potential we find,

$$\begin{aligned} E &= \frac{1}{2} \hbar \omega [3 \coth(\beta \hbar \omega) + \text{csch}(\beta \hbar \omega) - 2p_B + 1] \\ F &= \frac{1}{\beta} \ln \left[\frac{1}{8} \text{csch}^2 \left(\frac{\beta \hbar \omega}{2} \right) - \frac{1}{4} \text{csch}(\beta \hbar \omega) \right] - p_B \hbar \omega \\ S &= \frac{1}{2} k_B \beta \hbar \omega [3 \coth(\beta \hbar \omega) + \text{csch}(\beta \hbar \omega) + 1] \\ &\quad + k_B \ln \left[\frac{1}{8} \text{csch}^2 \left(\frac{\beta \hbar \omega}{2} \right) - \frac{1}{4} \text{csch}(\beta \hbar \omega) \right] \\ C &= \frac{1}{2} k_B \beta^2 \hbar^2 \omega^2 \text{csch}^2(\beta \hbar \omega) [\cosh(\beta \hbar \omega) + 3] \end{aligned} \quad (45)$$

Examining Eq. (45) we see that the internal energy and free energy are shifted by a constant proportional to p_B . This shift is a manifestation of the generalized exclusion principle for statistical anyons. As p_B varies from one to zero the lowest energy state of the system shifts from the bosonic limit, with both particles in the ground state of the oscillator, to the fermionic limit, with one particle in the ground state and the other in the first excited state. Notably both the entropy and heat capacity are independent of the statistics. Physically, this is a consequence of the fact that in the thermal equilibrium state both fermions and bosons have an equivalent, countably infinite, number of available states. Plots of the one-dimensional equilibrium thermodynamic quantities as a function of temperature are shown in Fig. 3.

2D Statistical anyons

If we ultimately wish to compare the thermodynamic behavior of statistical anyons with FES anyons, we must extend our thermodynamic analysis to two dimensions. Repeating the same approach for the case of a two-dimensional harmonic potential we find

$$\begin{aligned} E &= \hbar \omega \left[2 \coth \left(\frac{1}{2} \beta \hbar \omega \right) + \tanh \left(\frac{1}{2} \beta \hbar \omega \right) - p_B \tanh(\beta \hbar \omega) \right] \\ F &= -\frac{1}{\beta} \ln \left\{ \frac{1}{8} [\cosh(\beta \hbar \omega)]^{p_B} \text{csch}^2 \left(\frac{1}{2} \beta \hbar \omega \right) \text{csch}^2(\beta \hbar \omega) \right\} \\ S &= k_B \beta \hbar \omega \left[2 \coth \left(\frac{1}{2} \beta \hbar \omega \right) + \tanh \left(\frac{1}{2} \beta \hbar \omega \right) - p_B \tanh(\beta \hbar \omega) \right] \\ &\quad + k_B \ln \left\{ \frac{1}{8} [\cosh(\beta \hbar \omega)]^{p_B} \text{csch}^2 \left(\frac{1}{2} \beta \hbar \omega \right) \text{csch}^2(\beta \hbar \omega) \right\} \\ C &= \frac{1}{2} k_B \beta^2 \hbar^2 \omega^2 \left[2 \text{csch}^2 \left(\frac{1}{2} \beta \hbar \omega \right) - \text{sech}^2 \left(\frac{1}{2} \beta \hbar \omega \right) + 2p_B \text{sech}^2(\beta \hbar \omega) \right] \end{aligned} \quad (46)$$

In contrast to the one-dimensional case, we see that now the entropy and heat capacity now depend on p_B . The origin of this difference is clear if we think of the behavior of the entropy for two indistinguishable particles in the zero-temperature limit. For bosons there is only one available configuration, consisting of both particles in the ground state. In contrast, the fermion ground state is degenerate. The Pauli exclusion principle requires that one particle must be in the ground state and the other in the first excited state, but the excited state can be in either dimension. This degeneracy results in nonzero entropy in the limit $T \rightarrow 0$. Thus, for

Fig. 3 Equilibrium (A) internal energy, (B) free energy, (C) entropy, and (D) heat capacity for two statistical anyons in a one-dimensional harmonic potential with $p_B = 1$ (blue, dashed), $p_B = 1/2$ (red, solid), and $p_B = 0$ (green, dot-dashed).

Fig. 4 Equilibrium (A) internal energy, (B) free energy, (C) entropy, and (D) heat capacity for two statistical anyons in a two-dimensional harmonic potential with $p_B = 1$ (blue, dashed), $p_B = 1/2$ (red, solid), and $p_B = 0$ (green, dot-dashed).

statistical anyons the entropy varies smoothly between the boson and fermion limits as p_B changes from one to zero. Plots of the two-dimensional equilibrium thermodynamic quantities as a function of temperature are shown in Fig. 4.

2D FES anyons

For the case of two FES anyons in a harmonic potential the partition function has the following analytical form (Lerda, 1992; Myrheim, 1999)

$$Z_{TA} = \frac{e^{-\beta\hbar\omega(2+\nu)} + e^{-\beta\hbar\omega(4-\nu)}}{(1 - e^{-\beta\hbar\omega})^2 (e^{-2\beta\hbar\omega})^2}, \quad (47)$$

where ν is the anyonic phase parameter. Unlike the statistical anyon partition function, the FES partition function cannot be expressed as a function of the boson and fermion partition functions. In the two anyon problem, the anyonic phase can be interpreted as shifting the value of the relative motion angular momentum (Khare, 2005). Unlike GES and statistical anyons, the direction of rotation matters. Accounting for both possible exchange directions results in a multivalued wave function and leads to the two separate anyonic phase-dependent terms seen in the numerator of Eq. (47) (Myrheim, 1999).

As before, we determine the equilibrium internal energy, free energy, entropy, and heat capacity for the two FES anyon system by plugging Eq. (47) into Eq. (44) which yields

$$\begin{aligned} E &= \hbar\omega \left[\coth\left(\frac{1}{2}\beta\hbar\omega\right) + 2\coth(\beta\hbar\omega) + (\nu-1)\tanh(\beta\hbar\omega(1-\nu)) \right] \\ F &= \frac{1}{\beta} \ln \left[8 \operatorname{sech}(\beta\hbar\omega(\nu-1)) \sinh^2\left(\frac{1}{2}\beta\hbar\omega\right) \sinh^2(\beta\hbar\omega) \right] \\ S &= k_B \beta \hbar\omega \left[\coth\left(\frac{1}{2}\beta\hbar\omega\right) + 2\coth(\beta\hbar\omega) + (\nu-1)\tanh(\beta\hbar\omega(1-\nu)) \right] \\ &\quad + k_B \ln \left[\frac{1}{8} \cosh(\beta\hbar\omega(\nu-1)) \operatorname{csch}^2\left(\frac{1}{2}\beta\hbar\omega\right) \operatorname{csch}^2(\beta\hbar\omega) \right] \\ C &= \frac{1}{2} k_B \beta^2 \hbar^2 \omega^2 \left[\operatorname{csch}^2\left(\frac{1}{2}\beta\hbar\omega\right) + 4\operatorname{csch}^2(\beta\hbar\omega) + 2(\nu-1)^2 \operatorname{sech}^2(\beta\hbar\omega(\nu-1)) \right] \end{aligned} \quad (48)$$

In Fig. 5, we plot each thermodynamic quantity as a function of temperature. Qualitatively, the behavior is similar to that of statistical anyons. However, there are some notable differences. First, we see that the entropy for FES anyons converges to zero as $T \rightarrow 0$. This indicates the existence of a unique ground state configuration for all values of ν except $\nu = 1$. Furthermore, we see that at intermediate values of the anyonic phase parameter the heat capacity exceeds the bosonic value at low temperatures. Significantly, this indicates that the thermodynamic behavior of FES anyons is not confined to fall between that of bosons and fermions, as is the case for statistical anyons.

Comparing Figs. 4 and 5, we see that for the statistical anyons the line corresponding to $p_B = 1/2$ always remains evenly spaced between the bosonic and fermionic limits. This is expected as the statistical anyon energy spectrum is a weighted average over the bosonic and fermionic spectra which, in turn, leads to thermodynamic behavior that is evenly spaced between the bosonic and fermionic limits over all temperatures for $p_B = 1/2$. Conversely, for FES anyons the line corresponding to $\nu = 1/2$ bends more toward

Fig. 5 Equilibrium (A) internal energy, (B) free energy, (C) entropy, and (D) heat capacity for two FES anyons in a two-dimensional harmonic potential with anyon phase parameters $\nu = 0$ (blue, dashed), $\nu = 1/2$ (red, solid), and $\nu = 1$ (green, dot-dashed).

the fermionic limit as temperature increases. A consequence of this difference in thermodynamic behavior is that statistical anyons will retain their intermediate properties in higher temperature regimes.

Physically, the thermodynamic behavior of the FES anyons' has its roots in their hard-core nature and multivalued wave function. For harmonically confined FES anyons the energy, degeneracy, and level spacing all depend on ν (Myrheim, 1999; Khare, 2005). In the ground state, the energy eigenvalues corresponding to the two branches of the wave function only coincide in the fermionic limit, making $\nu = 1$ the only situation under which the ground state is degenerate and giving rise to the zero-temperature limit of the entropy observed in Fig. 5. At finite temperature the hard-core nature of FES anyons biases their thermodynamic behavior more toward the fermionic limit.

The behavior observed in the FES anyon heat capacity has similar physical origins. In the zero-temperature limit, the internal energy of FES anyons interpolates linearly between the bosonic and fermionic ground states, while at higher temperatures it converges to the fermionic behavior. This transition between an even average of the bosonic and fermionic behavior at zero temperature to near-fermionic behavior at higher temperatures necessitates a steeper positive slope of the internal energy at low temperatures than either bosons or fermions. This, in turn, leads to a heat capacity at intermediate values of ν that exceeds both bosons and fermions in this low-temperature transition region.

Thermodynamic equivalence

The previous results show that statistical and FES anyons display notably different thermodynamic behavior. However, with a parameter-dependent choice of the statistical mixture weights, it is possible to simulate the richer behavior of the FES anyons using the theoretically straightforward framework of statistical anyons.

The previously-examined thermodynamic behavior was derived entirely from the statistical and FES anyon partition functions. Setting the two partition functions (Eqs. 43 and 47) and solving for the statistical anyon parameter, p_B , yields

$$p_B = \frac{\ln[\cosh((\nu-1)\beta\hbar\omega)]}{\ln[\cosh(\beta\hbar\omega)]}. \quad (49)$$

We immediately see that this relationship between p_B and ν is dependent on the other physical parameters, namely, the inverse temperature and trapping frequency. However, if we take the high-temperature limit of Eq. (49), we find a simpler, parameter-independent relation,

$$p_B = (\nu-1)^2. \quad (50)$$

This approximation is exact in the limits of $\nu \rightarrow 0$ and $\nu \rightarrow 1$, which is expected as both statistical and FES anyons must converge to the same bosonic and fermionic limits. Eq. (50) is reminiscent of previous comparisons between Haldane's GES parameter and the topological anyon phase using the second Virial coefficient which also determined a quadratic polynomial relation (Murthy and Shankar, 1994a).

In Fig. 6, we plot the internal energy, free energy, entropy, and heat capacity for FES anyons, in comparison to statistical anyons with p_B chosen as given by Eq. (50). We see that the statistical and FES anyon behavior rapidly converges as temperature increases. However, the simplified relation between the anyon phase parameters does not capture the low-temperature behavior of the FES anyon heat capacity. To fully imitate this behavior, we must use Eq. (49). By plugging Eq. (49) into Eq. (44) we see that the equations of state for statistical and FES anyons become identical.

Detecting and manipulating FES anyons in two-dimensional materials is extremely challenging, which makes probing their thermodynamics difficult. Mimicking the thermodynamic behavior of FES anyons using statistical anyons provides a straightforward alternative approach, both as a model to test thermodynamic control of FES anyons or as a replacement in applications that would rely on their thermodynamics properties.

Fig. 6 Comparison of (A) internal energy, (B) free energy, (C) entropy, and (D) heat capacity of two FES anyons with phase parameter ν , against two statistical anyons using phase parameter $p_B = (\nu-1)^2$ for $\nu = 0$, $p_B = 1$ (blue, dashed), $\nu = 1$, $p_B = 0$ (green, dot-dashed), $\nu = 1/2$ (red, solid), and $p_B = 1/4$ (black, dotted).

Conclusion

Summary

In this chapter we have presented a dimension-independent formulation of anyons, “statistical anyons,” in which the anyonic properties arise from averaging over the behavior of a statistical mixture of bosons and fermions. We began by outlining an optical implementation of statistical anyons where the anyonic behavior manifests through a generalization of the HOM effect. Moving beyond quantum optics, we showed that the statistical anyon framework is equivalent to Haldane’s GES. Motivated by the statistical origins of the anyonic behavior, we compared the equilibrium thermodynamics of statistical and FES anyons. We demonstrated that, with a parameter-dependent choice of the anyonic phase, statistical anyons can exactly imitate the thermodynamic behavior of FES anyons.

Impacts and future directions

The framework of statistical anyons provides a tractable theoretical tool for studying anyonic behavior. It extends GES to a range of new experimental settings, including Bose–Fermi mixtures (Fang et al., 2011; Dehkharghani et al., 2017; Decamp et al., 2017; Fukuhara et al., 2009; Onofrio, 2016; Sowiński and García-March, 2019), optomechanical systems (Holmes et al., 2020), and surface plasmonics (Chen et al., 2018).

Statistical anyons, like the GES anyons they replicate, lack the non-Abelian properties necessary for implementing topological quantum computation. However, as demonstrated in Section “Thermodynamic equivalence,” they do provide an accessible tool for simulating the thermodynamic behavior of FES anyons. From a device-oriented standpoint, the role of anyonic behavior in the performance of quantum thermal machines has been studied both in the context of GES (Jaramillo et al., 2016; Beau et al., 2016) and statistical anyons (Myers and Deffner, 2021; Myers et al., 2021). Other thermodynamic properties of statistical anyons, such as the impact of anyonic statistics in Gibbs mixing (Yadin et al., 2020), remain to be explored. The framework of statistical anyons itself provides a range of possible new directions. The relationship between statistical anyons and other methods of generating anyonic behavior, including NOON states subject to Bloch oscillations (Lebugle et al., 2015), quasi-holes in Bose–Einstein condensates (Paredes et al., 2001), and black hole gasses (Strominger, 1993; Medvedev, 1997) is unknown. Finally, we note that the statistical anyon framework has only been applied for the case of an ensemble of noninteracting particles. In analogy to how the addition of an interparticle interaction can manifest GES in ideal bosons and fermions, it is possible that incorporating interactions may expand the state space of possible anyonic phases accessible to statistical anyons.

Abstract

Fractional Chern insulators (FCIs) are lattice generalizations of the conventional fractional quantum Hall effect (FQHE) in two-dimensional (2D) electron gases. They typically arise in a 2D lattice without time-reversal symmetry when a nearly flat Bloch band with nonzero Chern number is partially occupied by strongly interacting particles. Band topology and interactions endow FCIs exotic topological orders which are characterized by the precisely quantized Hall conductance, robust ground-state degeneracy on high-genus manifolds, and fractionalized quasiparticles. Since in principle FCIs can exist at zero magnetic field and be protected by a large energy gap, they provide a potentially experimentally more accessible avenue for observing and harnessing FQHE phenomena. Moreover, the interplay between FCIs and lattice-specific effects that do not exist in the conventional continuum FQHE poses new theoretical challenges. In this chapter, we provide a general introduction of the theoretical model and numerical simulation of FCIs, then pay special attention on the recent development of this field in moiré materials while also commenting on potential alternative implementations in cold atom systems. With a plethora of exciting theoretical and experimental progress, topological flat bands in moiré materials such as magic-angle twisted bilayer graphene on hexagonal boron nitride have indeed turned out to be a remarkably versatile platform for FCIs featuring an intriguing interplay between topology, geometry, and interactions.

Introduction

Restricting electrons in a two-dimensional (2D) plane penetrated by a uniform magnetic field and cooling the system to low temperature seems like a simple setup. However, it provides one of the most significant discoveries in condensed matter physics over the past half century. Remarkably, the Hall resistance R_H of this 2D electron gas (2DEG) has a novel dependence on the magnetic field B . Instead of increasing linearly with B as predicted by the classical theory, R_H develops multiple plateaus near proper rational filling ν , on which its value is precisely quantized at $R_H = h/(\nu e^2)$. Here h is the Planck constant, $-e$ is the electron charge, and $\nu = N/N_\phi$ with N and N_ϕ the number of electrons and magnetic flux quanta, respectively. This phenomenon is known as the quantum Hall effect (QHE). The plateaus near integer $\nu = n$, called the integer QHE (IQHE), were first discovered in 1980 by K. von Klitzing (Klitzing et al., 1980). These IQHE states can be understood in a single-particle picture: they result from the Landau quantization of an electron in the magnetic field, and correspond to n fully filled Landau levels (LLs). On the boundary, these n LLs come with n chiral edge modes. The precisely quantized R_H originates from a topological invariant—the Chern number $\mathcal{C}$ which is one for each LL (Thouless et al., 1982; Avron et al., 1983; Niu et al., 1985). This Chern number cannot change so long as the energy

gap in the bulk, which is the LL spacing in this case, does not close. This gives rise to the robustness of the IQHE plateaus. In this sense, the IQHE states are the first observed topological band insulators. By contrast, the QHE near fractional $\nu = f$, observed by Tsui and Störmer in 1983 (Tsui et al., 1982) and dubbed the fractional quantum Hall effect (FQHE), has a very different origin. As the single-particle states in each LL are exactly degenerate, it must be the electron-electron interaction that lifts the huge degeneracy in the partially filled LL and stabilize the FQHE. While this strongly correlated nature makes the FQHE notoriously difficult to study, it also endows the FQHE an exotic order: the intrinsic topological order (Wen, 1990), as characterized by non-trivial ground-state degeneracies depending on the genus of the manifold on which the FQH states reside (Wen and Niu, 1990), long-range entanglement (Kitaev and Preskill, 2006; Levin and Wen, 2006), and fractionalized quasiparticle excitations (Laughlin, 1983; Moore and Read, 1991; Feldman and Halperin, 2021). Motivated by understanding and utilizing exotic topological orders, the FQHE has grown to become one of the arguably most exuberant fields of modern condensed matter physics.

With more FQHE plateaus discovered in 2DEGs and deeper understanding obtained about the nature of observed states, relaxing the limitations of the strong magnetic field and ultralow temperature required to realize the FQHE remains a long-standing dream. In conventional 2DEG setups, $B \sim 15$ T and $T \lesssim 1$ K are necessary for the robust $\nu = 1/3$ plateau (Tsui et al., 1982). We need stronger magnetic fields to reach smaller fillings, and temperature of at least one order of magnitude lower and cleaner samples to see more fragile FQH states. Hence, a natural question arises: can we realize the FQHE at zero (at least much weaker) magnetic fields and higher temperature? Intuitively the solution to this question calls for a platform change. The first important step in this direction was provided by Haldane in his seminal work in 1988, where he constructed a simple tight-binding model on the honeycomb lattice and showed that the IQHE can exist in the lattice at zero net magnetic field (Haldane, 1988). In this model, the time-reversal symmetry (TRS) breaking caused by the magnetic field in the conventional IQHE is achieved by complex hopping which can be emulated by spin-orbit coupling in the lattice, and isolated Bloch bands carrying $C = \pm 1$ play the role of LLs. Such lattice versions of the conventional IQHE are now called Chern insulators, which were first reported in 2013 in thin films of chromium-doped (Bi, Sb)₂Te₃ (Chang et al., 2013) and later also in cold-atom systems (Jotzu et al., 2014).

Haldane's construction of Chern insulators raises the possibility of obtaining the FQHE in 2D lattice systems with broken TRS, dubbed fractional Chern insulators (FCIs), down to zero magnetic field. Of course, a lattice model should satisfy several conditions in order to host FCIs. The most natural requirement is a nearly flat Bloch band with nonzero Chern number, i.e., a nearly flat topological (Chern) band which can mimic an exactly flat LL in a 2DEG. The weak band dispersion enhances the interaction effect, so that intuitively interacting particles have a chance to form FQHE-like states when they partially occupy the band. Despite of important early work on FCIs, including the construction of a parent Hamiltonian in lattices containing only short range interactions and an exponentially decaying tail of hopping terms (Kapit and Mueller, 2010), the research in this direction became mainstream only in 2011 when it was emphasized that nearly flat Chern bands can exist in tight-binding models with strictly short-ranged hopping (Tang et al., 2011; Sun et al., 2011; Neupert et al., 2011). Subsequent numerical works indeed confirmed the existence of FCIs in various $|C| = 1$ flat bands as lattice analogs of conventional FQH states, including the Laughlin state, Moore-Read state, and hierarchy-composite-fermion series (Sheng et al., 2011; Regnault and Andrei Bernevig, 2011; Wang et al., 2011, 2012b; Wu et al., 2012a; Läuchli et al., 2013; Liu et al., 2013a). The adiabatic continuity between these FCIs and the corresponding conventional FQH states (Scaffidi and Möller, 2012; Wu et al., 2012b; Liu and Bergholtz, 2013; Wu et al., 2013) was established via mapping single-particle states in a Chern band to those in a LL (Qi, 2011; Wu et al., 2012b; Jian and Qi, 2013; Wu et al., 2013, 2014). Crucially, the energy gap protecting these FCIs may be greatly increased compared to conventional FQH states in 2DEGs, as it is determined by Coulomb interaction on the lattice scale rather than the magnetic length in 2DEGs which is typically two orders of magnitude larger. In fact, a naive estimate does not rule out FCIs at room-temperature (Tang et al., 2011).

The benefit of studying FCIs soon exceeds just finding lattice analogs of the already known conventional FQH states. The remarkable distinctions between a Chern band and a LL raise possibilities of new physics and meanwhile pose new challenges. Unlike for LLs, the quantum geometry (Berry curvature, Fubini-Study metric, etc.) of a Chern band is in general fluctuating in the Brillouin zone. Shortly after the first numerical identifications of FCIs, the key role played by this inhomogeneous quantum geometry on the stability of FCIs was noticed (Parameswaran et al., 2012; Roy, 2014; Jackson et al., 2015). Geometry might sound less important than topology, because under deformation of the band it is not invariant like Chern number even if the band keeps isolated. However, analytical and numerical analysis has unveiled it as a crucial criterion to judge how good a Chern band is for hosting FCIs. Thanks to the studies on FCIs, now we are understanding more about the effect of fluctuating band geometry on the many-body physics (Claassen et al., 2015; Wang et al., 2021; Parker et al., 2021; Varjas et al., 2022; Abouelkomsan et al., 2022), which is absent in the conventional FQHE due to the uniform geometry of a LL. Apart from the non-uniform quantum geometry, a Bloch band can support high Chern number $|C| > 1$ (Wang and Ran, 2011; Trescher and Bergholtz, 2012; Yang et al., 2012), while each LL can only carry $|C| = 1$. This lattice-specific feature implies qualitatively new FCI states beyond the FQH paradigm. Excitingly, plethora of such states have been confirmed in high Chern number bands (Liu et al., 2012; Wang et al., 2012a; Sterdyniak et al., 2013; Wu et al., 2013; Möller and Cooper, 2015; Wu et al., 2015; Bergholtz et al., 2015; Behrmann et al., 2016), but the complete understanding of them still needs more effort. Moreover, lattice defects in these high- C FCIs may act as worm-hole-like objects, suitably dubbed “genons”, that effectively change the genus of space and obey non-Abelian exchange statistics (Barkeshli and Qi, 2012; Barkeshli et al., 2013; Liu et al., 2017; Knapp et al., 2019; Liu and Bergholtz, 2019). This could lead to a new scheme of topological quantum computation.

The field of FCI has flourished over the last decade, motivated by its potential to manifest higher-temperature FQHE-like phenomena at much weaker magnetic fields and novel physics beyond the conventional FQHE. A main trend in the development of this field is to gather inspiration from other research fields, like material science and ultracold atoms, such that we can find suitable

lattice platforms to really produce FCIs in experiments. Remarkably, exciting progress has been made along this direction in recent years. The first experimental observation of FCI states was reported in 2018 for Bernal-stacked bilayer graphene, which, however, still needs a strong magnetic field of $B \sim 30$ T to create the required topological flat bands (Spanton et al., 2018). The rapid development of techniques to fabricate van-der-Waals heterostructures with moiré patterns (Geim and Grigorieva, 2013; Novoselov et al., 2016) provides new materials that can harbor intrinsic flat Chern bands at zero magnetic field (Zhang et al., 2019a), in which recent numerical works have identified the existence of zero-field FCIs (Abouelkomsan et al., 2020; Repellin and Senthil, 2020; Liu et al., 2021a; Parker et al., 2021). Consistent with earlier theoretical predictions (Abouelkomsan et al., 2020; Repellin and Senthil, 2020; Ledwith et al., 2020), multiple FCI states were indeed experimentally observed in 2021 with twisted bilayer graphene (TBG) (Bistritzer and MacDonald, 2011; Andrei and MacDonald, 2020) aligned with hexagonal boron nitride at weak magnetic fields down to 5 T (Xie et al., 2021b), in which the weak magnetic field was used only to improve the band geometry such that FCIs became favored. This experiment paves the way toward real zero-field FCIs, and meanwhile reports some exotic FCIs which need further investigation. Currently, the research on a broad range of moiré materials and the strongly-correlated phases thereof is making FCI an active field.

This chapter will provide a general introduction to the basic concepts, the methodology and the experimental observation of FCIs, mainly responding to the following questions: (i) what is the appropriate theoretical microscopic model to study FCIs? (ii) what conditions should this model satisfy to favor FCIs? (iii) how to identify FCIs and their competing phases in numerical simulations and experiments? (iv) how different FCIs are from the conventional FQHE? Meanwhile we will focus on the very recent development through our introduction. It is impossible to cover everything in this field within a chapter. For topics that are not discussed in detail, we recommend the readers to refer to earlier review articles (Parameswaran et al., 2013; Bergholtz and Liu, 2013; Neupert et al., 2015) and references therein.

Microscopic model

Here we present the general microscopic model for studying FCIs in 2D lattices with broken TRS. In most cases, we need to get a many-body Hamiltonian projected to a partially filled Bloch band to capture the low-energy physics within the band, in analogy to the LL projection in 2DEGs. There are two typical ways to achieve this in the literature, which we will describe below.

Tight-binding formalism

Tight-binding formalism is a common method to model particles in lattice systems. It is practical especially when the underlying lattice is not too complicated (i.e., only a few sites in each unit cell), and is highly relevant to cold atoms in optical lattices. This formalism has been used to study FCIs in various toy lattice models, like the kagome, checkerboard, and honeycomb lattice (Sheng et al., 2011; Regnault and Andrei Bernevig, 2011; Wang et al., 2011, 2012b; Wu et al., 2012a; Läuchli et al., 2013). Under the tight-binding scenario, it is natural to consider a many-body Hamiltonian of the form

$$H = \sum_{n,m} \sum_{\alpha,\beta} t_{nm}^{\alpha\beta} c_{n,\alpha}^\dagger c_{m,\beta} + \sum_{n,m} \sum_{\alpha,\beta} V_{nm}^{\alpha\beta} c_{n,\alpha}^\dagger c_{m,\beta}^\dagger c_{m,\beta} c_{n,\alpha}, \quad (1)$$

where $n, m = 1, \dots, N_u$ label the unit cells of the lattice at positions $\mathbf{R}_n$ and $\mathbf{R}_m$, $\alpha, \beta = 1, \dots, N_b$ label the internal states (for example, inequivalent sites) in each unit cell, and $c_{n,\alpha}^\dagger (c_{n,\alpha})$ creates (annihilates) a particle in unit cell $\mathbf{R}_n$ and state α . In Eq. (1), the first term is the single-particle Hamiltonian describing the hopping of particles in the lattice, and the second term is the two-body Hubbard-like interaction between particles. Translation invariance of both the hopping and the interaction is usually assumed, that is, $t_{nm}^{\alpha\beta}$ and $V_{nm}^{\alpha\beta}$ only depend on $\mathbf{R}_n - \mathbf{R}_m$. Then we can switch to the reciprocal space by the Fourier transform $c_{\mathbf{k},\alpha}^\dagger = \frac{1}{\sqrt{N_u}} \sum_n e^{i\mathbf{k} \cdot \mathbf{R}_n} c_{n,\alpha}^\dagger$, which creates a particle in state α with crystal momentum $\mathbf{k} = (k_x, k_y)$ restricted in the first Brillouin zone (1BZ) of the lattice. This reexpresses Eq. (1) as

$$H = \sum_{\mathbf{k} \in 1\text{BZ}} \sum_{\alpha,\beta} \mathcal{H}_0^{\alpha\beta}(\mathbf{k}) c_{\mathbf{k},\alpha}^\dagger c_{\mathbf{k},\beta} + \sum_{\{\mathbf{k}_i\} \in 1\text{BZ}} \sum_{\alpha,\beta} V_{\mathbf{k}_1\mathbf{k}_2\mathbf{k}_3\mathbf{k}_4}^{\alpha\beta} c_{\mathbf{k}_1,\alpha}^\dagger c_{\mathbf{k}_2,\beta}^\dagger c_{\mathbf{k}_3,\beta} c_{\mathbf{k}_4,\alpha}. \quad (2)$$

In Eq. (2), the single-particle and interaction matrix elements are

$$\mathcal{H}_0^{\alpha\beta}(\mathbf{k}) = \sum_n t_{n0}^{\alpha\beta} e^{-i\mathbf{k} \cdot \mathbf{R}_n} \quad (3)$$

and

$$V_{\mathbf{k}_1\mathbf{k}_2\mathbf{k}_3\mathbf{k}_4}^{\alpha\beta} = \frac{1}{N_u} \delta'_{\mathbf{k}_1+\mathbf{k}_2,\mathbf{k}_3+\mathbf{k}_4} \sum_n V_{n0}^{\alpha\beta} e^{-i(\mathbf{k}_1-\mathbf{k}_4) \cdot \mathbf{R}_n}, \quad (4)$$

respectively, where we have set $\mathbf{R}_m = \mathbf{0}$ and $\delta'_{\mathbf{k},\mathbf{k}'}$ is the 2D periodic Kronecker delta function with period of primitive reciprocal lattice vectors.

The single-particle band structure of the system can be extracted by diagonalizing the $N_b \times N_b$ matrix $\mathcal{H}_0^{z\beta}(\mathbf{k})$ for each $\mathbf{k} \in 1\text{BZ}$ separately. The resulting eigenvalues $\{\epsilon_s(\mathbf{k})\}$ are just the band energies, and the eigenvector $\psi_s(\mathbf{k})$ gives the Bloch state of the s -th band as $|\psi_s(\mathbf{k})\rangle = \sum_{\alpha} \psi_s^{\alpha}(\mathbf{k}) c_{\mathbf{k},\alpha}^{\dagger} |\text{vacuum}\rangle$. With the band eigenvectors at hand, one can define a new set of operators $\gamma_{\mathbf{k},s}^{\dagger}$ that create a particle with crystal momentum $\mathbf{k}$ in a specific band s , such that

$$\gamma_{\mathbf{k},s}^{\dagger} = \sum_{\alpha} \psi_s^{\alpha}(\mathbf{k}) c_{\mathbf{k},\alpha}^{\dagger} c_{\mathbf{k},\alpha}^{\dagger} = \sum_s [\psi_s^{\alpha}(\mathbf{k})]^* \gamma_{\mathbf{k},s}^{\dagger}. \quad (5)$$

In terms of $\gamma_{\mathbf{k},s}^{\dagger}$ and $\gamma_{\mathbf{k},s}$, one finds the many-body Hamiltonian Eq. (2) is rewritten as

$$H = \sum_{\mathbf{k} \in 1\text{BZ}} \sum_s \epsilon_s(\mathbf{k}) \gamma_{\mathbf{k},s}^{\dagger} \gamma_{\mathbf{k},s} + \sum_{\{\mathbf{k}_i\} \in 1\text{BZ}} \sum_{\{s_i\}} \sum_{\alpha,\beta} V_{\mathbf{k}_1 \mathbf{k}_2 \mathbf{k}_3 \mathbf{k}_4}^{\alpha\beta} \left[\psi_{s_1}^{\alpha}(\mathbf{k}_1) \right]^* \left[\psi_{s_2}^{\beta}(\mathbf{k}_2) \right]^* \psi_{s_3}^{\beta}(\mathbf{k}_3) \psi_{s_4}^{\alpha}(\mathbf{k}_4) \gamma_{\mathbf{k}_1,s_1}^{\dagger} \gamma_{\mathbf{k}_2,s_2}^{\dagger} \gamma_{\mathbf{k}_3,s_3} \gamma_{\mathbf{k}_4,s_4}. \quad (6)$$

The transform of the many-body Hamiltonian from Eq. (1) to Eq. (6) makes it convenient to deal with a situation that we are primarily interested in, that is, a single isolated band is partially filled by interacting particles while other bands are either fully occupied or empty. In this case, it makes sense to project the whole Hamiltonian to the partially filled band—this is where all the low-energy actions are expected to take place. Naively one may think this is valid only when the interaction strength is much smaller than the band gap such that band mixing is absent. However, the band projection actually works far beyond this limit as particles often prefer to restrict the low-energy actions in the partially filled band even if the interaction strength exceeds the band gap (Kourtis et al., 2014), similar to the situation in the conventional FQHE.

To do the band projection, we restrict the band indices in Eq. (6) to the partially filled band, reaching the projected Hamiltonian

$$H = \sum_{\mathbf{k} \in 1\text{BZ}} \epsilon(\mathbf{k}) \gamma_{\mathbf{k}}^{\dagger} \gamma_{\mathbf{k}} + \sum_{\{\mathbf{k}_i\} \in 1\text{BZ}} \bar{V}_{\mathbf{k}_1 \mathbf{k}_2 \mathbf{k}_3 \mathbf{k}_4} \gamma_{\mathbf{k}_1}^{\dagger} \gamma_{\mathbf{k}_2}^{\dagger} \gamma_{\mathbf{k}_3} \gamma_{\mathbf{k}_4}, \quad (7)$$

where we have dropped the band index for simplicity and

$$\bar{V}_{\mathbf{k}_1 \mathbf{k}_2 \mathbf{k}_3 \mathbf{k}_4} = \sum_{\alpha,\beta} V_{\mathbf{k}_1 \mathbf{k}_2 \mathbf{k}_3 \mathbf{k}_4}^{\alpha\beta} [\psi^{\alpha}(\mathbf{k}_1)]^* [\psi^{\beta}(\mathbf{k}_2)]^* \psi^{\beta}(\mathbf{k}_3) \psi^{\alpha}(\mathbf{k}_4). \quad (8)$$

Eq. (7) is the starting point in most literatures to investigate FCIs and other correlated phases occurring in lattice systems. In the flat-band limit where the band dispersion is sufficiently weak, we can even only keep the interaction term in Eq. (7). In this case, the band-projected Hamiltonian has almost the same form as the LL-projected Hamiltonian of the conventional FQHE, for which $\mathbf{k}$ is replaced by the orbital index of the LL.

Although majority of reported FCI states is captured by Eq. (7), exceptions beyond the single-band description exist. First, projection to multiple bands is necessary if an isolated set of bands is partially occupied, leading to multicomponent FCI states (Repellin et al., 2014; Zeng and Sheng, 2018; Zeng et al., 2019; Zeng, 2021; Zeng et al., 2022; Zeng and Zhu, 2022). The generalization of Eq. (7) to this case is straightforward. Second, sometimes strong interactions may dramatically modify the non-interacting band structure and produce an emergent Chern band in which FCIs can develop, even if the non-interacting band has zero Chern number or even not isolated (Simon et al., 2015; Zhu et al., 2016). We cannot rely on the single-band projection to study these states. For simplicity, we will not discuss these situations in this chapter.

Effective continuum model

Unlike in toy lattice models, realistic solid-state materials are often too complicated to be formulated as a simple tight-binding Hamiltonian. This is the case in moiré materials where a unit cell contains a few hundreds sites. For moiré systems, theorists usually rely on first-principle calculations to construct an effective continuum single-particle Hamiltonian H_0 in the reciprocal space to describe the low-energy bands (for instance, see Refs. Bistritzer and MacDonald, 2011; Zhang et al., 2019a,b; Lee et al., 2019; Haddadi et al., 2020; Chebrolu et al., 2019). We will give a concrete example of H_0 for twisted bilayer graphene in Section “FCIs in twisted bilayer graphene,” but here we give some general statements.

Like in the tight-binding formalism, the effective H_0 is also expressed in terms of the particle's creation and annihilation operators $c_{\mathbf{k},\alpha}^{\dagger}$ and $c_{\mathbf{k},\alpha}$, where α labels internal degrees of freedom of a particle. Similar to Eq. (5), $c_{\mathbf{k},\alpha}^{\dagger}$ and $c_{\mathbf{k},\alpha}$ can in turn be related to the band operators $\gamma_{\mathbf{k},s}^{\dagger}$ and $\gamma_{\mathbf{k},s}$ after diagonalizing H_0 . Regarding the two-body interaction in continuum, we can write it by the standard second-quantization formula as

$$H_{\text{int}} = \frac{1}{2} \sum_{\mathbf{q} \in R^2} \tilde{V}(\mathbf{q}) : \rho(\mathbf{q}) \rho(-\mathbf{q}) : , \quad (9)$$

where the summation of $\mathbf{q}$ is in the whole reciprocal space R^2 instead of only the 1BZ, $\tilde{V}(\mathbf{q}) = \frac{1}{A} \int V(\mathbf{r}) e^{-i\mathbf{q}\cdot\mathbf{r}} d\mathbf{r}$ is the Fourier transform of the interaction potential $V(\mathbf{r})$ with A the area of the 2D system, $\rho(\mathbf{q}) = \sum_{\alpha} c_{\mathbf{k}+\mathbf{q},\alpha}^{\dagger} c_{\mathbf{k},\alpha}$ is the density operator, and $::$ is the normal ordering. Then we can project the many-body Hamiltonian $H = H_0 + H_{\text{int}}$ to the partially filled band by the relation between $c_{\mathbf{k},\alpha}^{\dagger}$, $c_{\mathbf{k},\alpha}$ and $\gamma_{\mathbf{k},s}^{\dagger}$, $\gamma_{\mathbf{k},s}$ and restricting the band index s to the partially filled band. The obtained band-projected Hamiltonian has exactly the same form as Eq. (7).

Conditions of the existence of FCIs

Given the Hamiltonian Eq. (7) of interacting particles partially occupying a single isolated band, whether FCIs are favored as the ground states strongly depends on the system details, including the filling factor, the shape of the finite lattice, and properties of the band and the interaction. Insight of proper filling factors can be obtained in analogy to the conventional FQHE. For a finite lattice, we expect that its shape should be close to the 2D isotropic limit. In the following, we will summarize the known conditions which the band and the interaction should satisfy to harbor FCIs.

Requirements for the band

For a partially filled isolated band s , numerical works and analytical studies have identified three of its properties—bandwidth, topology, and quantum geometry, that are highly relevant to the existence of FCIs. The bandwidth W is determined by the band energies via $W = \max_{\mathbf{k}, \mathbf{k}' \in \text{1BZ}} [\epsilon_s(\mathbf{k}) - \epsilon_s(\mathbf{k}')]]$. By contrast, the topology and quantum geometry are encoded in band eigenstates (Cheng, 2010; Roy, 2014; Jackson et al., 2015; Ozawa and Mera, 2021). Denoting the cell periodic part of $|\psi_s(\mathbf{k})\rangle$ as $|u_s(\mathbf{k})\rangle$, the quantum geometric tensor of band s is defined as

$$\mathcal{Q}_s^{ab}(\mathbf{k}) = \langle \partial_{\mathbf{k}}^a u_s(\mathbf{k}) | \partial_{\mathbf{k}}^b u_s(\mathbf{k}) \rangle - \langle \partial_{\mathbf{k}}^a u_s(\mathbf{k}) | u_s(\mathbf{k}) \rangle \langle u_s(\mathbf{k}) | \partial_{\mathbf{k}}^b u_s(\mathbf{k}) \rangle \equiv g_s^{ab}(\mathbf{k}) - \frac{i}{2} \Omega_s^{ab}(\mathbf{k}) \quad (10)$$

with $a, b = x, y$. Up to a constant factor $-1/2$, the imaginary part of $\mathcal{Q}_s^{ab}(\mathbf{k})$ is just the Berry curvature

$$\Omega_s^{ab}(\mathbf{k}) = i [\langle \partial_{\mathbf{k}}^a u_s(\mathbf{k}) | \partial_{\mathbf{k}}^b u_s(\mathbf{k}) \rangle - \langle \partial_{\mathbf{k}}^b u_s(\mathbf{k}) | \partial_{\mathbf{k}}^a u_s(\mathbf{k}) \rangle] \quad (11)$$

which resembles the effect of magnetic field in reciprocal space. The band topology is then characterized by the integral of Berry curvature over the 1BZ, called Chern number

$$C_s = \frac{1}{2\pi} \int_{\text{1BZ}} \Omega_s^{xy}(\mathbf{k}) dk_x dk_y, \quad (12)$$

which must be an integer. Chern number is a topological invariant in the sense that it cannot be changed by modifying the band dispersion unless the band gap is closed. On the other hand, the real part of the quantum geometric tensor is the Fubini-Study (FS) metric

$$g_s^{ab}(\mathbf{k}) = \frac{1}{2} (\langle \partial_{\mathbf{k}}^a u_s(\mathbf{k}) | \partial_{\mathbf{k}}^b u_s(\mathbf{k}) \rangle - \langle \partial_{\mathbf{k}}^a u_s(\mathbf{k}) | u_s(\mathbf{k}) \rangle \langle u_s(\mathbf{k}) | \partial_{\mathbf{k}}^b u_s(\mathbf{k}) \rangle + a \leftrightarrow b) \quad (13)$$

of the band. As $|\langle u_s(\mathbf{k}) | u_s(\mathbf{k} + d\mathbf{k}) \rangle| \approx 1 - \frac{1}{2} g_s^{ab}(\mathbf{k}) dk_a dk_b$, the FS metric measures the distance between two $|u_s\rangle$ states at different $\mathbf{k}$ points. Moreover, the Berry curvature and the FS metric are related by two important inequalities (Parameswaran et al., 2013; Roy, 2014; Jackson et al., 2015; Claassen et al., 2015; Wang et al., 2021)

$$\text{tr} g_s^{ab}(\mathbf{k}) \geq |\Omega_s(\mathbf{k})|, \quad \det g_s^{ab}(\mathbf{k}) \geq \frac{1}{4} |\Omega_s(\mathbf{k})|^2, \quad (14)$$

the saturations of which are referred to as the trace condition and the determinant condition, respectively. In fact, the second inequality can be derived from the first one (Roy, 2014; Wang et al., 2021), thus the determinant condition is definitely satisfied when the trace condition is.

Considering the formation of the conventional FQHE in LLs, we naturally expect that the existence of FCIs builds on how well a Bloch band can reproduce the physics of a LL. In Table 1, we compare a Bloch band with a LL. Based on their differences in aspects of

Table 1 The comparison between a Landau level and a Bloch band from aspects of band dispersion, topology, quantum geometry, and PH asymmetry of the projected two-body interaction. Here we assume no disorder or boundary effects.

	Landau level	Bloch band
Dispersion	No dispersion, i.e., all single-particle states within each LL is perfectly degenerate.	Finite bandwidth in general.
Topology	Chern number $ C = 1$ for each LL. The sign is determined by the direction of the magnetic field.	Chern number of a Bloch band can be an arbitrary integer. Apart from $C = 0$ and $ C = 1$, there are also Bloch bands with higher Chern number $ C > 1$.
Quantum geometry	Uniform ($\mathbf{k}$ -independent) nonzero Berry curvature and FS metric. In particular, both inequalities in Eq. (14) are saturated for the lowest LL.	In general, both the Berry curvature and FS metric fluctuate in the 1BZ. While the trace and determinant conditions in Eq. (14) are satisfied for all two-band models at any $\mathbf{k}$ (Claassen et al., 2015; Wang et al., 2021), in general this does not hold for multiband models.
PH asymmetry of projected two-body interactions	No	Yes

dispersion, topology and quantum geometry, the following conditions appear to be necessary for a Bloch band to mimic a LL and host FQHE-like phenomena.

- **Bandwidth.** The bandwidth W should be smaller than the interaction strength V , such that the interaction dominates the physics. Otherwise, the ground state is expected to be a usual Fermi liquid of electrons or pile of bosons in the band bottom. Given a typical interaction scale in the system, it is easier to satisfy $W \ll V$ if the band is tuned to be flatter.
- **Band topology.** Typically we require that the band should carry nonzero Chern number, although this is not a fundamental necessity if strong interactions can induce an emergent Chern band (Simon et al., 2015; Kourtis, 2018). To get nonzero Chern number, we need to break the TRS, which can be achieved by complex hopping via spin-orbit coupling, ferromagnetism, artificial gauge fields, or interaction-induced spontaneous TRS breaking.
- **Band geometry.** The Berry curvature and FS metric should not strongly fluctuate in the 1BZ. Meanwhile, the trace and determinant conditions in Eq. (14) should be approximately satisfied if we need to mimic the lowest LL (LLL). The key role of band geometry on the stability of FCIs has been demonstrated in various lattice models, for instance, see Refs. Jackson et al. (2015), Wilhelm et al. (2021), Bauer et al. (2022) and Abouelkomsan et al. (2022).

One should note that, for a given lattice model, in general the smallest bandwidth, nonzero Chern number, and the most ideal band geometry cannot be achieved simultaneously by optimizing the model parameters. In fact, it has been proven that one cannot get topological bands with zero bandwidth by finite-range hopping (Chen et al., 2014). Even if one introduces infinite-range hopping to get an exactly flat topological band (Kapit and Mueller, 2010), its Berry curvature still fluctuates (Liu et al., 2013b). While perfectly flat band with exactly constant Berry curvature and finite Chern number can exist in multiband models (three or more bands) with infinite-range hopping, the trace and determinant conditions in Eq. (14) are not satisfied meanwhile (Varjas et al., 2022). For two-band models, both inequalities in Eq. (14) are saturated (Claassen et al., 2015; Wang et al., 2021), but the possibility of realizing exactly constant Berry curvature has been ruled out (Varjas et al., 2022). Therefore, we need to reach a compromise between the band dispersion, topology, and geometry when seeking “good” models to host FCIs. Over-optimizing one of those band properties does not always improve the stability of FCIs.

Requirements for the interaction

Generally speaking, interactions which decay fast with distance, like the onsite interaction (for bosons), Hubbard-like interactions between the nearest neighboring (NN) or next NN sites, long-range Coulomb and dipolar interactions, often work well to stabilize Abelian FCIs. However, for non-Abelian FCIs, one need to tune the interaction carefully, or even use less realistic manybody interactions. More rigorously, in analogy to what is done in the FQH case, we can use the lattice version of Haldane’s pseudopotentials (Haldane, 1983) to predict what kind of interactions may stabilize a specific FCI state. These pseudopotentials on the lattice can be evaluated through the two-particle energy spectrum of the interaction (Läuchli et al., 2013; Bergholtz and Liu, 2013; Liu et al., 2013b) or the mapping between the LLL and the lattice Wannier functions (Lee et al., 2013).

Particle-hole asymmetry

Having stated the requirements for the band and the interaction separately, we now turn to another key condition for the emergence of FCI states, whose satisfaction is determined jointly by the band and interaction properties. This condition originates from different behavior of the projected Hamiltonian Eq. (7) under particle-hole (PH) transformation in a Bloch band from that in a LL. Under the standard PH transformation of fermions $\gamma_{\mathbf{k}}^{\dagger} \leftrightarrow \gamma_{\mathbf{k}}$, Eq. (7) transforms to

$$H \rightarrow \sum_{\mathbf{k} \in 1\text{BZ}} \epsilon_h(\mathbf{k}) \gamma_{\mathbf{k}}^{\dagger} \gamma_{\mathbf{k}} + \sum_{\{\mathbf{k}_i\} \in 1\text{BZ}} \bar{V}_{\mathbf{k}_1 \mathbf{k}_2 \mathbf{k}_3 \mathbf{k}_4} \gamma_{\mathbf{k}_1}^{\dagger} \gamma_{\mathbf{k}_2}^{\dagger} \gamma_{\mathbf{k}_3} \gamma_{\mathbf{k}_4} \quad (15)$$

up to a constant, which includes a hole-hole interaction term similar to that of electrons and a single-hole dispersion

$$\epsilon_h(\mathbf{k}) = -\epsilon(\mathbf{k}) + \sum_{\mathbf{k}' \in 1\text{BZ}} (\bar{V}_{\mathbf{k}\mathbf{k}'\mathbf{k}'} + \bar{V}_{\mathbf{k}'\mathbf{k}\mathbf{k}'} - \bar{V}_{\mathbf{k}\mathbf{k}'\mathbf{k}'} - \bar{V}_{\mathbf{k}'\mathbf{k}\mathbf{k}'}) \equiv -\epsilon(\mathbf{k}) + \epsilon_h^i(\mathbf{k}). \quad (16)$$

Remarkably, apart from the contribution from the band dispersion $\epsilon(\mathbf{k})$ of electrons, holes experience an additional dispersion $\epsilon_h^i(\mathbf{k})$ originating from the interaction. In a LL, one can prove that ϵ_h^i is simply a constant shift (chemical potential) for two-body interactions (Möller and Simon, 2005), which, together with the exact degeneracy of LL orbitals, means both electrons and holes in a LL experience the same zero dispersion (although this does not hold for multi-body interactions). However, $\epsilon_h^i(\mathbf{k})$ generically varies with $\mathbf{k}$ in a Bloch band even for two-body interactions (Läuchli et al., 2013; Liu et al., 2013b), because the interaction matrix element $\bar{V}_{\mathbf{k}_1 \mathbf{k}_2 \mathbf{k}_3 \mathbf{k}_4}$ in general lacks translational invariance in the reciprocal space of the lattice. This PH asymmetry, i.e., electrons and holes experience different dispersions, is a lattice-specific feature of the projected Hamiltonian in a Bloch band. As the strength of the PH asymmetry is quantified by the bandwidth of $\epsilon_h^i(\mathbf{k})$, we need a weakly dispersive $\epsilon_h^i(\mathbf{k})$ to simulate the LL physics on the many-body level. In fact, the bandwidth of $\epsilon_h^i(\mathbf{k})$ is also closely related to the homogeneity of FS metric via

$$\epsilon_h^i(\mathbf{k}) \approx \sum_{\mathbf{q}} \tilde{V}(\mathbf{q}) e^{-\sum_{ab} q_a q_b g^{ab}(\mathbf{k})} \quad (17)$$

when the product of the interaction $\tilde{V}(\mathbf{q})$ and the band form factor $\langle \psi(\mathbf{k}) | \psi(\mathbf{k} - \mathbf{q}) \rangle$ decay fast with $|\mathbf{q}|$ (Abouelkomsan et al., 2022).

We can see the importance of uniform band geometry and weakly dispersive $\epsilon_h^i(\mathbf{k})$ from Eq. (17). Similar to FQH states in a LL, FCIs prefers nearly uniform particle density and Berry curvature in the 1BZ, so that all particles can feel an approximately constant effective magnetic field. In narrow bands, the distribution of particles in the 1BZ is greatly affected by $\epsilon_h^i(\mathbf{k})$: $\mathbf{k}$ points with small (large) $\epsilon_h^i(\mathbf{k})$ tend to be occupied by holes (electrons). Therefore, if the FS metric is sufficiently uniform in a narrow band, the particles have no priorities to occupy the 1BZ, which, together with an approximately constant Berry curvature, should stabilize FCIs. Otherwise, strongly fluctuating FS metric will distribute electrons to regions with larger $\epsilon_h^i(\mathbf{k})$ even when the bandwidth of $\epsilon(\mathbf{k})$ is small. Such non-uniform density can destabilize the FCI phase, and can even completely destroy it if the Berry curvature happens to be weak in these regions (Wilhelm et al., 2021; Abouelkomsan et al., 2022). We will discuss phases competing against FCIs caused by this mechanism in Section “Competing phases.” The crucial dependence of the many-body ground state on the band geometry is absent in LLs due to the uniform geometry there. In fact, flattening band geometry is one of the main challenges for realizing FCIs in experiments.

Numerical diagnosis of FCIs

The conditions listed in the previous section serve as guiding principles to search for suitable candidate lattice models harboring FCIs. However, to quantitatively judge whether a candidate model is really good, we need to extract the low-energy physics of Eq. (7) by numerical techniques such as exact diagonalization (ED) and density matrix renormalization group (DMRG). In this section, we will discuss how to diagnose FCIs by numerical simulations. We will give numerical identifications not only for FCIs, but also for some competing phases. A concrete example in twisted bilayer graphene will be presented in the next section.

Basic identifications

The standard numerical approach to explore the low-energy physics of Eq. (7) is to diagonalize the many-body Hamiltonian for a partially filled band of a finite system, consisting of N particles and N_1 and N_2 unit cells in the two primary directions of the lattice, then extract information from the obtained low-lying energy levels and eigenstates. Here the band filling is defined as $\nu \equiv N/(N_1 N_2)$, and interacting particles can either be electrons in solid materials or bosons in cold-atom setups. Some common methods for identifying FCIs’ topological orders from numerical data are listed below. Depending on the method, the finite system is often put on the torus or the cylinder geometry.

- Topological degeneracy.** The most obvious numerical evidence of FCIs is the topological degeneracy of incompressible (i.e., gapped) ground states on the torus, i.e., in a 2D system with periodic boundary conditions in both directions. This can be directly examined in the low-lying energy spectrum returned by numerical diagonalization, thus is usually the first thing to confirm in most literatures. In analogy to the conventional FQHE, at least q approximately degenerate ground states are expected for FCIs at band filling $\nu = p/q$, where p and q are coprime (multicomponent and non-Abelian FCIs have ground-state degeneracies larger than q). These ground states should carry momenta that match the Haldane statistics characterizing the candidate FCIs (Regnault and Andrei Bernevig, 2011; Andrei Bernevig and Regnault, 2012; Wu et al., 2014). In general, the FCI ground-state degeneracies are not exact for finite systems due to the symmetry reduction compared to the conventional FQHE. However, the ground-state manifold should be separated from excited levels by a many-body gap that does not vanish in the thermodynamic limit and, ideally, the ground state splitting should vanish exponentially with the increasing of system size. Moreover, The ground-state degeneracy should be insensitive to the boundary conditions, which can be demonstrated by calculating the spectral flow under insertion of magnetic flux through the handle of the torus. Typically, the FCI ground states evolve into each other in the spectral flow for an appropriate flux insertion but do not mix with higher excited levels.
- Entanglement measures.** Besides energetic evidence, one can rely on entanglement spectroscopies for more insights into the nature of the ground states. Such entanglement information is entirely extracted from the numerically obtained ground-state wavefunctions. For a bipartition of a 2D topologically ordered state in real space, the entanglement entropy between the two subsystems obeys an area law, with a subleading term encoding the quantum dimensions of quasiparticles (Kitaev and Preskill, 2006; Levin and Wen, 2006). Numerical evaluation of this subleading term, dubbed topological entropy, for the ground state can distinguish FCIs from trivial phases (Grushin et al., 2015; Gerster et al., 2017; Andrews et al., 2021a; Andrews and Soluyanov, 2020). Moreover, the entanglement spectrum (ES) (Li and Haldane, 2008) of the ground state, i.e., the whole spectrum of the reduced density matrix of one subsystem, contains more information than the entanglement entropy. For the real-space bipartition, the counting structure in the low-lying ES (Liu et al., 2013c; Andrews et al., 2021a; Zhu et al., 2016; Motruk et al., 2016; Luo et al., 2020, 2021; Andrews et al., 2021b; Andrews and Soluyanov, 2020) is the same as that of edge excitations (He et al., 2020; Luo et al., 2013; Kjäll and Moore, 2012), thus providing a fingerprint of the underlying topological order according to the bulk-edge correspondence. One can also bipartite the system by dividing all particles into two parts. The corresponding particle-cut ES (PES) (Sterdyniak et al., 2011) encodes the physics of bulk quasihole excitations in its low-lying part, which has been extensively used to identify FCIs (Regnault and Andrei Bernevig, 2011; Scaffidi and Möller, 2012; Sterdyniak et al., 2012; Andrei Bernevig and Regnault, 2012; Wu et al., 2012a; Liu et al., 2013a, 2012; Sterdyniak et al., 2013; Li et al., 2014; Wang et al., 2013; Repellin et al., 2014; Behrmann et al., 2016; Simon et al., 2015; Sterdyniak et al., 2015; Abouelkomsan et al., 2020; Liu et al., 2021a; Kupczyński et al., 2021; Wang and Liu, 2022).

- *Hall conductance.* As another hallmark, the quantized fractional Hall conductance is achieved when the ground state is in the FCI phase. The Hall conductance is proportional to the ground-state Chern number (Thouless et al., 1982; Niu et al., 1985), which can be evaluated by twisting the boundary conditions on the torus (Wang et al., 2011, 2012b; Gerster et al., 2017; Zeng and Sheng, 2018; Zeng et al., 2019; Zeng, 2021; Zeng et al., 2022; Zeng and Zhu, 2022; Okamoto et al., 2022). Alternatively, for systems on the cylinder surface one can perform a numerical flux insertion through the hole of the cylinder and determine the Hall conductance by measuring the charges pumped from one edge to the other edge of the cylinder, which can be easily implemented in DMRG simulations (Zaletel et al., 2014; Grushin et al., 2015; Andrews et al., 2021a; Zhu et al., 2016; Motruk et al., 2016; Andrews et al., 2021b; Wang et al., 2022; Zeng and Sheng, 2018; Zeng et al., 2019; Zeng, 2021; Zeng et al., 2022; Luo et al., 2021; Zeng and Zhu, 2022; Andrews and Soluyanov, 2020).
- *Quasiparticle statistics.* The fractional statistics of quasiparticles is a characterizing feature of FCI states. One can directly simulate the generation and braiding of quasiparticles to demonstrate their fractional statistics (Liu et al., 2015; Rodríguez and Nielsen, 2015; Mantas Račiūnas et al., 2018; Manna et al., 2018; Jaworowski et al., 2019; Macaluso et al., 2020; Srivatsa et al., 2021; Wang et al., 2022). Alternatively, the statistics is encoded in the so called modular matrix (Verlinde, 1988; Wen, 1990). We can numerically evaluate these matrices from the ground-state wavefunctions by constructing the minimally entangled states in the ground-state manifold for bipartitions of the lattice along different directions (Zhang et al., 2012; Zhu et al., 2013, 2014, 2016; Liu and Bergholtz, 2019).

Competing phases

FCI is only one possibility among various phases that can potentially exist in a Chern band. Competing phases prevail when the microscopic details of the system disfavor FCIs, which often happens when the conditions listed in Section “Conditions of the existence of FCIs” are not satisfied. Studying the competition of FCIs with other candidate phases is crucial for determining the stable regions of FCIs in experiments. In the following, we discuss two common competing phases and their features which can be observed in numerical simulations.

- *Crystalline phases.* The competition in 2DEGs between conventional FQH states and charge density waves (CDWs), like Wigner crystals and stripe phases, has been known for long (Fukuyama et al., 1979; Yoshioka and Lee, 1983; Moessner and Chalker, 1996; Rezayi et al., 1999; Haldane et al., 2000; Yang et al., 2001). Both CDWs and FQH states rely on the presence of strong interactions, however, the formers spontaneously break the translational symmetry. Similarly, when the interaction dominates in topological flat bands, the competition between CDWs and FCIs is also typically expected at fillings that are commensurate with the lattice. Indeed, such competition has been confirmed in various flat-band models (Wang et al., 2011; Varney et al., 2010; Kourtis et al., 2012; Grushin et al., 2012; Li et al., 2014; Kourtis and Daghofer, 2014; Kourtis et al., 2017; Kourtis, 2018; Luo et al., 2020; Wilhelm et al., 2021; Jaworowski et al., 2018; Kupczyński et al., 2021; Parker et al., 2021; Abouelkomsan et al., 2022; Hu and Liu, 2022). Apparently, the formation of these states requires proper filling factor, interaction, and lattice shape. Recently, the studies of FCIs in moiré systems found that strongly fluctuating quantum geometry also facilitates the formation of CDWs by distributing particles to specific regions of the 1BZ (Wilhelm et al., 2021; Parker et al., 2021; Abouelkomsan et al., 2022).

CDWs are characterized by their specific charge orders. In numerical simulations, this order can be revealed most prominently by calculating the structure factor

$$S(\mathbf{q}) = \frac{1}{N_1 N_2} \langle (\rho(\mathbf{q}) \rho(-\mathbf{q})) \rangle - N^2 \delta_{\mathbf{q},0}, \quad (18)$$

which is the Fourier transform of the static density-density correlation function. Here the average $\langle \rangle$ is over the ground state. When the charge order develops, $S(\mathbf{q})$ should manifest pronounced peaks at the order momenta.

These order momenta are reciprocal vectors of the real-space modulation of charge density. By contrast, $S(\mathbf{q})$ of FCI states is expected to be featureless due to the absence of charge order. Regarding the low-energy many-body spectra, the CDW phase is accompanied by the ground-state degeneracy that corresponds to all possible charge configurations for a given charge order. Unlike the FCIs, the momenta of degenerate CDW states are separated by the order momenta instead of being determined by the Haldane statistics (occasionally these may coincide such that further diagnostics are needed to settle the nature of the states).

- *Fermi liquids.* Generally speaking, there are two types of Fermi liquid (FL) that can emerge in a partially filled Bloch band. The first one is usual, caused by the strong dispersion of electron band $\epsilon(\mathbf{k})$. This type of state can be identified by the Fermi surface structure in the dependence of electron's ground-state occupation $n(\mathbf{k})$ on $\epsilon(\mathbf{k})$ at momentum point $\mathbf{k}$, that is, $n(\mathbf{k})$ suddenly drops from ≈ 1 to ≈ 0 at some critical $\epsilon(\mathbf{k})$. The possibility of this usual FL phase can be ruled out when the electron band is very flat.

The second type of FL phase is much less intuitive. As we showed in Eqs. (15) and (16), holes experience an additional dispersion $\epsilon_h^i(\mathbf{k})$ induced by interactions, which may be strongly dispersive even in a narrow electron band. If $\epsilon_h^i(\mathbf{k})$ dominates over the hole-hole interaction in a narrow electron band, FL becomes a good candidate for the ground state of holes, which still renders FL a natural ground-state candidate for electrons even if they do not feel strong band dispersion. Unlike the usual FL, this new FL is a correlated phase, as $\epsilon_h^i(\mathbf{k})$ is contributed by the interaction in flat bands. It should be characterized by a strong correlation between $n(\mathbf{k})$ and $\epsilon_h^i(\mathbf{k})$: $n(\mathbf{k})$ is small (large) at $\mathbf{k}$ points with small (large) $\epsilon_h^i(\mathbf{k})$ which tend to be occupied (unoccupied) by holes. Also, the

Fermi sea structure is expected to appear in the $n(\mathbf{k}) - \epsilon_h^i(\mathbf{k})$ curve, which provides a fingerprint for the this unusual FL phase in numerical simulations.

Intuitively, one may expect that the interaction-driven FL phase in narrow electron bands dominates over FCIs at high electronic band fillings. Indeed, this was confirmed in several toy models, where FCIs are replaced by the FL states at band filling $\nu \gtrsim 2/3$ (Läuchli et al., 2013; Bergholtz and Liu, 2013). However, in some moiré flat bands this unusual FL phase was found to prevail in a much wider range of ν down to $\nu = 1/3$, where FCIs are totally absent (Abouelkomsan et al., 2020, 2022). This can be understood by the very strong $\epsilon_h^i(\mathbf{k})$ originating from the far-from-flat quantum geometry of these bands, as shown in Eq. (17).

FCIs in twisted bilayer graphene

After a general discussion of numerical identifications of FCI states and their competing phases, we now use twisted bilayer graphene (TBG) as a concrete example to show how these identifications work. Recent developments have picked moiré flat bands in TBG as promising platforms to host FCIs.

Microscopic model of TBG

TBG consists of two sheets of monolayer graphene with a twist angle θ in between (Andrei and MacDonald, 2020). At small twist angles $\theta \lesssim 10^\circ$, the difference between commensurate and incommensurate structures can be ignored, and the twisting leads to a moiré pattern of spatial periodicity $a_M = a/(2 \sin(\theta/2)) \gg a$ (Fig. 1(a)), where $a = 0.246$ nm is the lattice constant of monolayer graphene. The enlargement of the spatial periodicity corresponds to folding of original graphene 1BZ into much smaller moiré BZ (MBZ) (Fig. 1(b)). The low-energy states reside in the MBZs near the Dirac points $\mathbf{K}^\pm$ of monolayer graphene, called as two valleys of TBG which are related by time-reversal conjugation. At small twist angles, weak effects like intervalley scattering and spin-orbit coupling are negligible, leading to valley and spin degeneracy of each moiré band. The non-interacting low-energy band structure near the charge neutrality point (CNP) thus consists of four degenerate valence bands and four degenerate conduction bands, labeled by their valley index $+$, $-$ and spin index $\uparrow$, $\downarrow$. By convention the filling is chosen as $\nu = 0$ at CNP, such that $\nu = -4$ ($\nu = +4$) when these eight bands are all empty (occupied). At a set of magic angles (Bistritzer and MacDonald, 2011; Tarnopolsky et al., 2019), valence and conduction bands become flat (Bistritzer and MacDonald, 2011; Lopes dos Santos et al., 2012, 2007; Tarnopolsky et al., 2019), however, still touch each other. This Dirac band touching is protected by the combination of C_{2z} rotation symmetry and time-reversal ($\mathcal{T}$) symmetry. On the single-particle level, the band gap can be opened by alignment with hexagonal boron nitride (hBN) which breaks the $C_{2z}\mathcal{T}$ symmetry. In this case, the valence and conduction bands for each fixed valley and spin flavors are isolated and may carry opposite Chern numbers $C = \pm 1$ in opposite valleys (Hunt et al., 2013; Jung et al., 2015; Song et al., 2019; Liu et al., 2019; Po et al., 2019; Zhang et al., 2019a,b), however, the valley and spin degeneracies of band energies remain. While it is complicated to predict how electrons occupy these degenerate bands when ν changes from -4 to $+4$ (Kang and Vafeek, 2019; Liu and Dai, 2021; Repellin et al., 2020b; Xie et al., 2021a), recent theoretical studies found that interactions are able to lift the valley and spin degeneracies under suitable circumstances (Repellin et al., 2020b; Bultinck et al., 2020; Liu and Dai, 2021; Xie et al., 2021a). When this happens, we have a simple picture in which the eight spin and valley polarized bands are sequentially filled, giving rise to Chern insulating states at integer fillings. These Chern insulators at integer ν are indeed observed in experiments down to zero magnetic field (Zondiner et al., 2020; Nuckolls et al., 2020; Wu et al., 2021; Saito et al., 2021; Das et al., 2021; Choi et al., 2021; Park et al., 2021; Stepanov et al., 2021; Serlin et al., 2020; Pierce et al., 2021).

The above results motivate the investigation of interactions within a single band of TBG with fixed spin and valley flavors (Abouelkomsan et al., 2020; Repellin and Senthil, 2020; Wilhelm et al., 2021; Parker et al., 2021). To proceed, we assume that the top and bottom graphene layers are rotated by, $\pm\theta/2$, respectively, and hBN is aligned with the top layer. We focus on the valence

Fig. 1 (a) TBG moiré pattern in real space, whose periodicity is given by vectors $\mathbf{a}_1^M = a_M(\sqrt{3}/2, 1/2)$ and $\mathbf{a}_2^M = a_M(\sqrt{3}/2, 1/2)$. (b) The moiré Brillouin zone (MBZ) of TBG. Two large hexagons (green and orange) are original first Brillouin zones of top and bottom graphene layers. The small red hexagon represents the MBZ resulting from twist. The $\mathbf{K}_{t,b}^{\pm}$ points, the vectors $\mathbf{q}_{0,1,2}$ and the MBZ reciprocal lattice vectors $\mathbf{G}_1$ and $\mathbf{G}_2$ are given. (c) Low-energy band structure of TBG-hBN for $\theta = 1.30^\circ$, $M = 20$ meV along a trajectory in the reciprocal space shown as the inset. The valence and conduction band (blue) near CNP carries Chern number $C = -1$ and $C = 1$, respectively.

band of valley $\mathbf{K}^+$. At small twist angles ($a_M \gg a$), the band information is encoded in an effective single-particle continuum Hamiltonian (Bistritzer and MacDonald, 2011; Zhang et al., 2019a,b)

$$H_0 = \sum_{\mathbf{k}} \mathbf{c}_t^\dagger(\mathbf{k}) h_{-\theta/2}(\mathbf{k} - \mathbf{K}_t^+) \mathbf{c}_t(\mathbf{k}) + \sum_{\mathbf{k}} \mathbf{c}_b^\dagger(\mathbf{k}) h_{\theta/2}(\mathbf{k} - \mathbf{K}_b^+) \mathbf{c}_b(\mathbf{k}) \\ + \sum_{\mathbf{k}} \sum_{j=0}^2 \left(\mathbf{c}_t^\dagger(\mathbf{k} - \mathbf{q}_0 + \mathbf{q}_j) T_j \mathbf{c}_b(\mathbf{k}) + h.c. \right) + M \sum_{\mathbf{k}} \mathbf{c}_t^\dagger(\mathbf{k}) \sigma_z \mathbf{c}_t(\mathbf{k}), \quad (19)$$

where $\mathbf{c}_{t/b}(\mathbf{k}) = \begin{pmatrix} c_{A_t/b}(\mathbf{k}) \\ c_{B_t/b}(\mathbf{k}) \end{pmatrix}$ are spinors of annihilation operators for electrons with momentum $\mathbf{k}$ in top (t) and bottom (b) graphene layers, respectively, and A and B label the two sublattices of single-layer graphene. Note that $\mathbf{k}$ in H_0 is near the $\mathbf{K}^+$ valley, but not restricted in the MBZ. The first two terms in H_0 are just the standard Dirac Hamiltonians of top and bottom graphene layers, for which $h_\theta(\mathbf{k}) = h(R_\theta \mathbf{k})$ with $h(\mathbf{k}) = -(\sqrt{3}at_0/2)(k_x \sigma_x + k_y \sigma_y)$, $t_0 = 2.62$ eV, and R_θ the counter-clockwise rotation around the z -axis in the momentum space. To the lowest order of approximation, the alignment of hBN induces an onsite potential of strength M (the last term in H_0) on the top graphene layer, where we have neglected the weaker effect from the moiré pattern formed between the top layer graphene and hBN (Zhang et al., 2019b). A rough estimation gives $M \approx 15$ meV (Zhang et al., 2019b), however, larger values like $M = 30$ meV were also used in theoretical studies (Xie et al., 2021b; Parker et al., 2021), so we choose $M = 20$ meV throughout this section. The moiré tunneling between two graphene layers (the third term in H_0) is given by $T_j = w_0 - w_1 e^{i(2\pi/3)j\sigma_x} e^{-i(2\pi/3)j\sigma_z}$ with $\mathbf{q}_0 = \mathbf{k}_t^+ - \mathbf{k}_b^+$, $\mathbf{q}_1 = R_{2\pi/3}\mathbf{q}_0$ and $\mathbf{q}_2 = R_{-2\pi/3}\mathbf{q}_0$ (Fig. 1(b)), where w_0 and w_1 are the interlayer tunneling strengths between AA and AB sites, respectively. w_0 is smaller than w_1 because of lattice relaxation (Popov et al., 2011; Nam and Koshino, 2017; Uchida et al., 2014; van Wijk et al., 2015; Koshino et al., 2018). Theoretical calculations and experimental measurements suggest $w_0/w_1 = 0.5-0.8$ (Koshino et al., 2018; Xie et al., 2019; Guinea and Walet, 2019; Das et al., 2021), hence we choose $w_0 = 0.7w_1$ in this section, where w_1 is fixed as 110 meV according to *ab initio* numerics (Jung et al., 2014). For each $\mathbf{k}_0 \in \text{MBZ}$, the moiré band structure in the MBZ can be obtained by writing $\mathbf{k}$ in H_0 as $\mathbf{k} = \mathbf{k}_0 + m\mathbf{G}_1 + n\mathbf{G}_2$ with integers $m, n = -d, \dots, d$ then diagonalizing H_0 , where $\mathbf{G}_1$ and $\mathbf{G}_2$ are the MBZ primitive reciprocal lattice vectors (Fig. 1(b)) and d is a cutoff typically set as $d = 5-9$. In Fig. 1(c), we show the low-energy band structure at $\theta = 1.30^\circ$, where the flat valence and conduction bands near CNP have Chern number $\mathcal{C} = \mp 1$, respectively.

Regarding the interaction, we consider a dual-gate setup to mimic experiments, in which electrons experience the gate-screened Coulomb interaction, whose Fourier transform reads

$$\tilde{V}(\mathbf{q}) = \frac{e^2}{4\pi\epsilon A} \frac{2\pi \tanh(\xi q/2)}{q}, \quad (20)$$

where ϵ is the dielectric constant of the material and ξ is the distance between the top and bottom gates. Based on typical parameters in TBG experiments, we choose $\epsilon = 4\epsilon_0$ (Bessler et al., 2019; Guinea and Walet, 2018) with ϵ_0 the vacuum dielectric constant and scan ξ between a_M and $2a_M$ (Saito et al., 2020; Stepanov et al., 2020).

The total Hamiltonian projected to the valence band has the same form as Eq. (7), in which $\mathbf{k}$'s should be now restricted in the MBZ and $\epsilon_{\mathbf{k}}$ is the valence band dispersion. The matrix elements of the projected interaction are

$$\bar{V}_{\mathbf{k}_1\mathbf{k}_2\mathbf{k}_3\mathbf{k}_4} = \frac{1}{2} \delta'_{\mathbf{k}_1+\mathbf{k}_2, \mathbf{k}_3+\mathbf{k}_4} \sum_{\mathbf{G}} \tilde{V}(\mathbf{k}_1 - \mathbf{k}_4 + \mathbf{G}) \langle \psi(\mathbf{k}_1) | \psi(\mathbf{k}_4 - \mathbf{G}) \rangle \langle \psi(\mathbf{k}_2) | \psi(\mathbf{k}_3 + \mathbf{G} + \delta\mathbf{G}) \rangle, \quad (21)$$

where $\mathbf{G}$ is summed over the entire reciprocal space instead of MBZ only, $\delta\mathbf{G} = \mathbf{k}_1 + \mathbf{k}_2 - \mathbf{k}_3 - \mathbf{k}_4$, and $|\psi(\mathbf{k})\rangle$ is the valence band eigenvector. One may further account the effects of remote bands in the mean-field level by adding extra single-particle terms (Andrei Bernevig et al., 2021; Xie et al., 2021a; Parker et al., 2021), however, we neglect this issue to avoid technical complexity in this tutorial introduction.

Numerical evidence of FCIs

With the microscopic many-body Hamiltonian projected to the valence band of the $\mathbf{K}^+$ valley, we can run extensive ED calculations on the torus geometry to search for numerical identifications of FCI states, as discussed in Section “Numerical diagnosis of FCIs.” We do this in the parameter space spanned by $\theta \in [1.0^\circ, 1.6^\circ]$ and $\xi/a_M \in [1, 2]$, in which the valence band is always isolated and carries Chern number $\mathcal{C} = -1$. The system has a finite size, consisting of N electrons on the $N_1 \times N_2$ moiré lattice. Considering that robust FCIs at one-third band filling were observed in various $|\mathcal{C}| = 1$ flat bands (Sheng et al., 2011; Regnault and Andrei Bernevig, 2011; Wu et al., 2012a; Läuchli et al., 2013), we choose $\bar{\nu} \equiv N/(N_1 N_2) = 1/3$ filling of the valence band and expect the emergence of lattice analogs of the Laughlin FQH state (Laughlin, 1983).

First of all, provided all eigenvalues $\{E_n\}$ of the many-body Hamiltonian returned by ED have been sorted in ascending order, the threefold degeneracy of incompressible FCI ground states can be probed by the FCI gap $\Delta_{\text{FCI}} \equiv E_4 - E_1$ and the FCI splitting $W_{\text{FCI}} \equiv E_3 - E_1$. If the lowest three eigenstates are not in momentum sectors predicted by the Haldane statistics of the Laughlin state, we simply set $\Delta_{\text{FCI}} = 0$. The numerical data of scanning Δ_{FCI} and $\Delta_{\text{FCI}}/W_{\text{FCI}}$ in the (θ, ξ) parameter space for $N = 10$ electrons are demonstrated in Fig. 2(a) and (b), from which we can identify a wide range of parameters supporting nice threefold degeneracies

Fig. 2 Numerical data in the $\theta - \xi$ parameter space of TBG-hBN. (a) The FCI gap Δ_{FCI} and (b) the quality of FCI degeneracy $\Delta_{\text{FCI}}/W_{\text{FCI}}$ for $N = 10$ electrons in the valence band of $N_1 \times N_2 = 5 \times 6$ moiré lattice. (c) Band geometry of the valence band, including the Berry curvature fluctuation $\sigma(\Omega)$, the FS metric fluctuation $\sigma(g)$, and the deviation δ_v from the saturated trace condition. (d) Bandwidths of the valence band (W) and the interaction-induced hole dispersion (W_h). The shades in (c) and (d) indicates the range of twist angle in which robust FCIs exist. In (a), we give a tentative phase diagram. As shown later, the CDW phase is identified by the structure factor, and the usual Fermi liquid (FL)-like phase is characterized by the step structure in the $n(\mathbf{k}) - \epsilon(\mathbf{k})$ curve.

in the momentum sectors of the Laughlin state. This region slightly expands in the θ direction from $\theta \in [1.20^\circ, 1.35^\circ]$ to $\theta \in [1.20^\circ, 1.40^\circ]$ with the increasing of ξ from a_M to $2a_M$ (weaker screening).

Having obtained the threefold degeneracy for $N = 10$ electrons as preliminary evidence of the $\bar{\nu} = 1/3$ FCI, we analyze the numerical data more carefully at a representative parameter point $(\theta, \xi) = (1.27^\circ, 2a_M)$ in this region (Fig. 3). First, the dependence of the degeneracy on the system size and the boundary condition should be examined. The energy spectra of different system sizes, plotted vs the many-body momentum (K_1, K_2), are presented in Fig. 3(a), in which the threefold degeneracy in the momentum sectors predicted for the Laughlin state appear for all system sizes. Moreover, this degeneracy persists under magnetic flux insertion through the handles of the toroidal system (Fig. 3(c)). A finite-size scaling of Δ_{FCI} and W_{FCI} suggests that both the threefold degeneracy and the groundstate gap are very likely to survive in the thermodynamic limit (Fig. 3(b)). Note that the gap extrapolating to the $1/N \rightarrow 0$ limit goes to ~ 2 meV, corresponding to a temperature which is an order of magnitude higher than required by the conventional FQHE in 2DEGs. The nontrivial topological properties of the ground state can be further corroborated by the PES, whose levels $\{\lambda_n\}$ are labeled by the total momentum (K_1^A, K_2^A) of the subsystem with N_A electrons. Strikingly, an entanglement gap appears in the PES (Fig. 3(d)), the number of levels below which exactly matches the counting of quasichole excitations in the Laughlin state (Regnault and Andrei Bernevig, 2011).

Both the low-energy spectrum and entanglement spectroscopy strongly indicate that lattice analogs of the continuum $\nu = 1/3$ Laughlin state exist in the valence band of TBG-hBN. We can even establish their adiabatic continuity by using the mapping between single-particle states in a Chern band and in the LLL. Such mapping has been constructed either between lattice Wannier states and LLL orbitals in the Landau gauge (Qi, 2011; Wu et al., 2012b; Jian and Qi, 2013; Wu et al., 2014), or between lattice Bloch states and LLL Bloch-like basis (Wu et al., 2013). In fact, TBG in the so called chiral limit (Tarnopolsky et al., 2019) allows to build a more explicit correspondence between $|C| = 1$ Chern bands with *ideal geometry* and the LLL. To reach this limit, we need to set $w_0 = 0$ such that the single-particle Hamiltonian possesses chiral symmetry $\sigma_z H_0 \sigma_z = -H_0$, where σ_z is the Pauli matrix acting on the sublattice. While it is a drastic approximation to decrease w_0 to zero even in the presence of lattice relaxation, the magic angle phenomena of TBG can already be well captured in the chiral limit: the entire valence and conduction bands near CNP become perfectly flat at a set of twist angles when $w_0 = 0$, which is the origin of the nearly flat bands observed at magic angles with finite w_0 (Tarnopolsky et al., 2019). In the presence of chiral symmetry, the magic-angle TBG (MATBG) flat bands gains ideal quantum geometry (Ledwith et al., 2020), that is, the Berry curvature does not change sign and varies in sync with the FS metric via

$$g^{ab}(\mathbf{k}) = \frac{1}{2} \delta^{ab} |\Omega(\mathbf{k})|, \quad (22)$$

Fig. 3 Numerical evidence of the $\bar{\nu} = 1/3$ FCI in the valence band of TBG-hBN at a representative parameter point $(\theta, \xi) = (1.27^\circ, 2a_M)$. (a) The low-lying energy spectra for $N = 8, 10, 12$ electrons on the $N/2 \times 6$ lattice. The shade indicates the threefold ($D = 3$) topological degeneracy of the ground states. (b) The finite-size scaling of the energy gap $E_4 - E_1$ and the ground-state splitting $E_3 - E_1$ for $N = 4, 5, 6, 8, 10, 12$ electrons. (c) The spectral flow for $N = 10$, $N_1 \times N_2 = 5 \times 6$, where Φ_y is the magnetic flux insertion in the $\mathbf{a}_2^M$ direction. (d) The particle entanglement spectrum for $N = 10$, $N_1 \times N_2 = 5 \times 6$ and $N_A = 5$, with 23,256 levels below the entanglement gap (the dashed line).

in the entire MBZ, where δ^{ab} is the identity matrix. In this situation, both inequalities in Eq. (14) are saturated, just like in the LLL (see (Mera and Ozawa, 2021) for a systematic method to construct bands with ideal quantum geometry). Moreover, the real-space forms $\psi_{\mathbf{k}}(\mathbf{r})$ of flat-band wave functions in chiral MATBG are fixed by the ideal quantum geometry as (Wang et al., 2021)

$$\psi_{\mathbf{k}}(\mathbf{r}) = \mathcal{N}_{\mathbf{k}} \mathcal{B}(\mathbf{r}) \varphi_{\mathbf{k}}(\mathbf{r}), \quad (23)$$

where $\mathcal{N}_{\mathbf{k}}$ is the normalization factor, $\mathcal{B}(\mathbf{r})$ is a $\mathbf{k}$ -independent function, and $\varphi_{\mathbf{k}}(\mathbf{r})$ is the Bloch-like basis in the LLL. Remarkably, Eq. (23) does not only hold for chiral MATBG, but is valid for all $|\mathcal{C}| = 1$ bands with the ideal quantum geometry (Wang et al., 2021). Starting from this relation in the single-particle level, one can also generalize Haldane pseudopotentials from the LLL to ideal $|\mathcal{C}| = 1$ flat bands and construct model FCIs as zero-energy ground states of short-ranged interactions (Ledwith et al., 2020; Wang et al., 2021). Zero-energy FCIs were also observed in other models (Kapit and Mueller, 2010; Liu et al., 2013b; Behrmann et al., 2016, which implies that the band geometry is also ideal there. The ideal band geometry and model FCIs are also expected in chiral MATBG at a finite magnetic field (Sheffer and Stern, 2021).

Back to our numerical results in TBG-hBN, the stabilization of the $\bar{\nu} = 1/3$ FCI phase is closely related to whether the conditions listed in Section “Conditions of the existence of FCIs” are satisfied. To see this, we characterize quantum geometry of the valence band by fluctuations of the Berry curvature $\Omega(\mathbf{k})$ and FS metric $g^{ab}(\mathbf{k})$ and the violation of the saturated trace condition, as quantified by

$$\begin{aligned} \sigma(\Omega) &= \sqrt{\langle \Omega^2(\mathbf{k}) \rangle - \langle \Omega(\mathbf{k}) \rangle^2}, \\ \sigma(g) &= \sqrt{\sum_{a,b=x,y} (\langle g^{ab}(\mathbf{k}) g^{ba}(\mathbf{k}) \rangle - \langle g^{ab}(\mathbf{k}) \rangle \langle g^{ba}(\mathbf{k}) \rangle)}, \\ \delta_{\text{tr}} &= \langle \text{tr} g^{ab}(\mathbf{k}) - |\Omega(\mathbf{k})| \rangle, \end{aligned} \quad (24)$$

respectively, where $\langle O(\mathbf{k}) \rangle = \frac{1}{A_{\text{MBZ}}} \int_{\text{MBZ}} O(\mathbf{k}) d\mathbf{k}$ is the average of quantity O in the MBZ, with A_{MBZ} the area of MBZ. We plot $\sigma(\Omega)$, $\sigma(g)$, δ_{tr} together with the bandwidth W of the electron’s valence band and the bandwidth W_h^i of interaction-induced hole dispersion $\epsilon_h^i(\mathbf{k})$ in Fig. 2(c) and (d) as a function of twist angle θ . Remarkably, the most robust FCI states indeed appear when all of these quantities are sufficiently small. Nevertheless, the minima of these quantities, are not located at the same θ , so over-minimizing one quantity does not necessarily improve the stability of the FCI phase. In particular, the robust FCIs appear at twist angles slightly above the TBG magic angle. These numerical results are consistent with the requirements listed in Section “Conditions of the existence of FCIs.”

Numerical evidence of competing phases

As we discussed before, competing phases will prevail when properties of the microscopic model disfavor FCI states. In our numerical data, the FCI phase obviously breaks down when the twist angle is either reduced or increased out of the optimal range in Fig. 2. On the left side of the FCI phase (with smaller θ), there is a pronounced sensitivity of the energy spectrum to the lattice size. In particular, when both N_1 and N_2 are divisible by three, we observe a new kind of threefold ground-state degeneracy appearing in equally spaced momentum sectors rather than in $\bar{\nu} = 1/3$ Laughlin FCI sectors. For example, at a representative parameter point $(\theta, \xi) = (1.10^\circ, 2a_M)$ in this region, the three ground states of $N = 12$, $N_1 \times N_2 = 6 \times 6$ appear in the $(K_1, K_2) = (0, 0)$, $(2, 2)$ and $(4, 4)$ sectors (Fig. 4(a)). By contrast, the ground states in the FCI phase of the same system size are all located in the $(K_1, K_2) = (0, 0)$ sector (Fig. 3(a)).

Fig. 4 Numerical evidence of competing phases in the valence band of TBG-hBN. (a) The low-lying energy spectrum of the CDW phase at a representative parameter point $(\theta, \xi) = (1.10^\circ, 2a_M)$. The three ground states are separated by the order momenta $\Delta \mathbf{K} = (2, 2)$ and $(4, 4)$. (b) The structure factor $S(\mathbf{q})$ of the CDW state at the same parameter point as in (a). (c) The ground-state occupation $n(\mathbf{k})$ of electrons vs the electron band dispersion in the usual FL phase at a representative parameter point $(\theta, \xi) = (1.60^\circ, 2a_M)$. We choose $N = 12$ electrons at $\bar{\nu} = 1/3$ in the $N_1 \times N_2 = 6 \times 6$ lattice in (a)–(c). (d) The ground-state occupation $n(\mathbf{k})$ of electrons vs the interaction-induced hole dispersion $\epsilon_h^i(\mathbf{k})$ at the parameter point $(\theta, \xi) = (1.10^\circ, 2a_M)$ for fillings $\bar{\nu} = 1/3, 2/3$ and $4/5$. The corresponding system sizes are $N = 12$, $N_1 \times N_2 = 6 \times 6$, $N = 24$, $N_1 \times N_2 = 6 \times 6$, and $N = 28$, $N_1 \times N_2 = 5 \times 7$, respectively.

Distribution of degenerate ground states over equally spaced momenta is a signal of CDWs. As we discussed in Section “Competing phases,” this can be further confirmed by the structure factor $S(\mathbf{q})$. Indeed, pronounced peaks of $S(\mathbf{q})$ exist at the corners of the MBZ (Fig. 4(b)), revealing the underlying phase is the CDW with the order momentum $\mathbf{K}_{t,b}^*$. These order momenta are indeed those separating the degenerate ground states, by noting $\Delta\mathbf{K} = (2, 2) = (\mathbf{G}_1 + \mathbf{G}_2)/3 \sim \mathbf{K}_b^*$ and $\Delta\mathbf{K} = (4, 4) = 2(\mathbf{G}_1 + \mathbf{G}_2)/3 \sim \mathbf{K}_t^*$. Here $\sim$ means “equal to” up to a MBZ primitive reciprocal lattice vector. The order momenta suggest a tripled unit cell of charge modulation compared to the original moiré lattice (Wilhelm et al., 2021). The identification of order momenta also explains the absence of the CDW phase when either N_1 or N_2 are indivisible by three. Remember that the single-electron momentum $\mathbf{k}$ can only take $\mathbf{k} = \frac{m_1}{N_1}\mathbf{G}_1 + \frac{m_2}{N_2}\mathbf{G}_2$ for a finite periodic system. Hence both N_1 and N_2 must be divisible by three if $\mathbf{K}_{t,b}^*$ belong to this set of allowed $\mathbf{k}$.

On the other hand, on the right side of the FCI phase (larger θ), neither the FCI degeneracy nor the CDW degeneracy appears in the low-energy spectra, no matter what the lattice size is. Note that in this region the electron bandwidth dramatically increases while the interaction-induced hole bandwidth remains small (Fig. 2(d)), implying that the ground state is a usual FL. Indeed, we find a sharp step in the electronic occupation number $n(\mathbf{k})$ at some critical $\epsilon(\mathbf{k})$, as shown in Fig. 4(c).

To see the unusual interaction-induced FL phase, we need to check the region in which the interaction-induced hole dispersion is much stronger than electron dispersion. Therefore, we choose the parameter point $(\theta, \xi) = (1.10^\circ, 2a_M)$ where this condition is satisfied (Fig. 2(d)). Remarkably, we do find the emergence of a Fermi-surface structure in the $n(\mathbf{k}) - \epsilon_h^i(\mathbf{k})$ with the increasing of the filling factor from $1/3$ to $4/5$ (Fig. 4(d)). This means the K-CDW phase at $\bar{\nu} = 1/3$ is replaced by the unusual FL phase at large fillings.

FCIs in Bloch bands with high Chern numbers

As listed in Table 1, a significant qualitative difference of a Chern band from a LL is that it can support higher Chern number $|C| > 1$. In general, one can add longer-range hopping in a $|C| = 1$ model or appropriately stack multilayers of $|C| = 1$ models to get $|C| > 1$ bands (Wang and Ran, 2011; Zhang et al., 2011; Trescher and Bergholtz, 2012; Yang et al., 2012; Sticlet and Piéchon, 2013; Wu et al., 2015; Behrmann et al., 2016; Zhang et al., 2019a; Chittari et al., 2019; Lee et al., 2019). This strategy also works for moiré materials. One can systematically construct $|C| = n$ bands near the CNP by twisting two sheets of Bernal-stacked n graphene layers (Wang and Liu, 2022; Ledwith et al., 2022). TBG corresponds to the $n = 1$ case. $n = 2$ gives the twisted double bilayer graphene (TDBG), for which $|C| = 2$ flat bands near the CNP have been confirmed (Zhang et al., 2019a; Lee et al., 2019; Chebrolov et al., 2019). Strikingly, the model constructed in this way gains chiral symmetry for any $n \geq 1$ if only intersublattice couplings are kept. At magic angles, these chiral models all possess perfectly flat valence and conduction bands with ideal band geometry.

FCIs can be diagnosed in high-Chern number bands by the same identifications as in $|C| = 1$ models. Excitingly, series of high- C FCI states have been numerically discovered in realistic moiré bands (Liu et al., 2021a; Wang and Liu, 2022) inspired by earlier numerical findings in tight-binding toy models (Yang et al., 2012; Wang et al., 2012a; Liu et al., 2012; Wang et al., 2013; Sterdyniak et al., 2013; Wu et al., 2013; Bergholtz et al., 2015; Wu et al., 2015; Behrmann et al., 2016; Möller and Cooper, 2015; Andrews and Möller, 2018). These FCIs appear at band fillings, for instance,

$$\nu = \frac{k}{|C|(m-1) + 1} \quad (25)$$

with integer $k \geq 1$ and $m \geq 2$. Here $k = 1$ and $k > 1$ correspond to Abelian and non-Abelian states, respectively, and m is even (odd) for bosons (fermions). Further fillings of high-CFCIs can be predicted by applying the composite-fermion theory to Hofstadter bands (Möller and Cooper, 2015). Some of the observed high-CFCIs are even model states occurring as the zero-energy ground states of proper short-ranged interactions (Behrmann et al., 2016; Wang and Liu, 2022).

Ample attention has been directed toward understanding these high-CFCIs. Intuitively, they may have a relation with the conventional FQH states in $|C|$ copies of the LLL, which also carry Chern number C as a whole. However, an obvious discrepancy exists between a single Chern number C band and $|C|$ copies of the LLL: the number of single-particle orbitals in the latter must be divisible by $|C|$ as each LLL contains an integer number of orbitals, while the number of single-particle states in the former does not necessarily to be a multiple of $|C|$. To resolve this discrepancy, a new type of $|C|$ -component LLL was proposed. Here component refers to internal degrees of freedom of particles, like spin or physical layer. In contrast to the usual multicomponent LLL where the $|C|$ components are decoupled, a new set of boundary conditions, called “color-entangled” boundary conditions, is adopted to connect different components, i.e., a particle can change its component index when crossing the boundary of the system (Wu et al., 2013, 2014). Under this scenario, one can construct a single manifold of Bloch-like states with Chern number C , rather than $|C|$ separate Chern-number-one manifolds, such that the number of orbitals per LLL does not need to be an integer. Diagonalizing Haldane’s pseudopotentials in the “color-entangled” LLL basis produces unconventional FQH states, which were found to have high overlaps and the same PES countings with high-CFCIs in lattice models (Wu et al., 2013). However, the analytical ansatz wavefunctions of the high-CFCIs are still unknown, and it remains unclear whether the color-entangled boundary conditions lead to new topological orders compared with conventional $|C|$ -component FQH states.

Experimental observation of FCIs

We have seen that FCIs arise from the interplay between interactions and the dispersion, topology, and geometry of the partially filled band. Therefore, their experimental realizations likely require highly controllable platforms in which band properties and interactions can be easily tuned to the suitable regime. Given this, van-der-Waals heterostructures with moiré patterns (Geim and Grigorieva, 2013; Novoselov et al., 2016) naturally emerge as a promising candidate to host FCIs. There are many experimental knobs in this kind of setups that can affect band properties and interactions, including the twist angle, the external fields, the dielectric environment, and even the material itself. In the past few years, rapid progress has been made on manufacturing van-der-Waals heterostructures and investigating the exotic correlated phases thereof.

Experiment in Bernal-stacked bilayer graphene

The first observation of FCI states was reported in a van-der-Waals heterostructure made of Bernal-stacked bilayer graphene aligned with hBN (BLG-hBN), penetrated by a perpendicular magnetic field $B \sim 30$ T (Spanton et al., 2018). In this system, electrons experience a moiré superlattice potential from the mismatched graphene and hBN lattices. The interplay between the magnetic field and the moiré potential creates topological Harper-Hofstadter bands that act as parents of potential FCI states. By determining the compressibility of the system via measuring the penetration field capacitance for variable electron density n_e and magnetic flux density n_ϕ per moiré superlattice cell, multiple incompressible states are identified along trajectories obeying Streda formula

$$n_e = tn_\phi + s, \quad (26)$$

where $t = \sigma_{xy}h/e^2$ is the dimensionless Hall conductance and s is the zero-field filling factor Streda (1982); MacDonald (1983).

The observed incompressible states can be distinguished by their values of t and s (see Table 2): non-integer t signals intrinsic topological order whereas fractional s may originate from either topological order or translational symmetry (TS) breaking. Remarkably, apart from the trivial states, QHE states in LLs, and Chern insulators in Hofstadter bands, clear evidence of states with fractional s and fractional t was observed in the experiment, which correspond to FCIs. These FCI states develop from electron/hole doping the nearby parent Chern insulating states with an effective filling $\bar{\nu}$ in the partially filled band. Some of them exist in a $C = -1$ band at $\bar{\nu} = 1/3, 2/3, 2/5, 3/5$, falling into the odd-denominator Laughlin and composite fermion sequence. Notably, several other states exist in a $C = 2$ band, for instance, at $\bar{\nu} = 1/3$ and $\bar{\nu} = 1/6$. The $C = 2, \bar{\nu} = 1/3$ state, with $(t, s) = (8/3, -1/3)$, preserves TS of the moiré superlattice and belongs to the sequence predicted in Ref. Möller and Cooper (2015). However, the $C = 2, \bar{\nu} = 1/6$ state carries $(t, s) = (7/3, -1/6)$, which means that only half fundamental charge $e/3$ is bound to each moiré unit cell. This feature suggests doubling of unit cell in the electron density distribution which spontaneously breaks TS of the moiré superlattice. The TS-broken FCI, as well as the observed TS-broken Chern insulators, imply an intriguing hybridization of conventional CDW and topological phase. Such combination of CDW and topological features is also numerically discovered in $C = 0, \pm 1, 2$ bands of several toy tight-binding models (Kumar et al., 2014; Kourtis and Daghofer, 2014; Kourtis, 2018) and experimentally observed in other moiré materials (Pierce et al., 2021; Polshyn et al., 2022). The hybrid states in $|C| = 2$ bands may originate from ferromagnetism of internal degree of freedoms and their entanglement with real-space translation in high Chern number bands (Kumar et al., 2014; Polshyn et al., 2022).

Table 2 The observed incompressible states in Refs. Spanton et al. (2018) and Xie et al. (2021b) classified by their values of t and s . While some of the observed Chern insulators and FCIs preserve translational symmetry (TS) of the moiré superlattice, others spontaneously break this symmetry with an expanded unit cell of electron density distribution, implying an intriguing combination of conventional charge density wave and topological features. Those exotic fractional Chern insulators in the last row are neither simple TS preserving nor TS broken states, and may originate from the interplay between the multicomponent nature of the material and the spatial symmetry.

Incompressible states	Values of t and s
Trivial correlated insulator	$t = 0$ and integer $s \neq 0$
Charge density wave	$t = 0$ and fractional s
Integer quantum Hall states in LLs	Integer $t \neq 0$ and $s = 0$
TS-preserving Chern insulators	Integer $t \neq 0$ and integer $s \neq 0$
TS-broken Chern insulators (also observed in Refs. Pierce et al. (2021) and Polshyn et al. (2022))	Integer $t \neq 0$ and fractional s
Fractional quantum Hall states in LLs	Fractional t and $s = 0$
TS-preserving fractional Chern insulators	Fractional t and fractional s , t and s have the same denominator
TS-broken fractional Chern insulators	Fractional t and fractional s , denominator of s is a multiple of that of t
Exotic fractional Chern insulators	Fractional t and fractional s , t and s have coprime denominators

Experiment in twisted bilayer graphene

While the experiment above realizes the FCI states in the sense that they have no direct LL counterparts, a quite high magnetic field is still needed to produce the topological band structure. Therefore, to turn the dream of zero-field FCI into reality, we must find systems hosting intrinsic topological flat bands in the absence of (or at least with weak) external magnetic fields. As predicted by theoretical works (Zhang et al., 2019a; Song et al., 2019; Liu et al., 2019; Po et al., 2019; Zhang et al., 2019b), TBG appears as a promising candidate to satisfy this requirement. A plethora of recent experiments down to zero field (Zondiner et al., 2020; Nuckolls et al., 2020; Wu et al., 2021; Saito et al., 2021; Das et al., 2021; Choi et al., 2021; Park et al., 2021; Stepanov et al., 2021; Serlin et al., 2020; Pierce et al., 2021) have confirmed the existence of Chern insulating states at integer band fillings, thus indeed raising the possibility of realizing zero-field FCIs in TBG systems.

A significant progress was made in this direction in which FCI states were observed in TBG aligned with hBN at weak magnetic fields as low as ~ 5 T (Xie et al., 2021b). In this experiment, TBG devices were prepared near the magic twist angle $\theta \sim 1.06^\circ$, then a perpendicular magnetic field is applied. Local electronic compressibility measurements were performed using a scanning single-electron transistor. Similar to the BLG-hBN experiment (Spanton et al., 2018), the dependence of this compressibility on the electron density and magnetic field, as shown in Fig. 5(a), reveals a large number of incompressible states (Table 2) satisfying Eq. (26), in which multiple FCI states with fractional t and s are identified. Remarkably, the first two FCI states appear in the range of $3 < \nu < 4$ at a weak magnetic field of only ~ 5 T [state 1 with $(t, s) = (2/3, 10/3)$ and state 2 with $(t, s) = (1/3, 11/3)$ in Fig. 5(b)]. According to their (t, s) values, these two states are formed at $\bar{\nu} = 1/3$ and $\bar{\nu} = 2/3$ filling of a $C = -1$ band and preserve the TS of the moiré superlattice, thus they can be interpreted as lattice analogs of the $\nu = 1/3$ Laughlin FQH state and its particle-hole conjugate. The energy gaps for both states are estimated as ~ 0.6 K, which is comparable to the typical temperature required to realize Laughlin states in 2DEGs. Notably, these two FCI states are suddenly replaced by CDWs with the decreasing of the magnetic field. Numerical simulations in Refs. Xie et al. (2021b) and Parker et al. (2021) interpreted this phenomenon in terms of quantum geometry of the partially filled band: the applied magnetic field flattens the band Berry curvature, such that favorable band geometry conditions for the emergence of FCIs are created. However, unlike in the BLG-hBN experiment where the whole Chern band is created by the

Fig. 5 Incompressible states observed in TBG-hBN. (a) Local inverse compressibility $d\mu/dn$ as a function of electron filling ν and the magnetic field B . Those red trajectories correspond to incompressible states. (b) Wannier diagram extracted from the experimental data in (a). Black lines correspond to integer quantum Hall states/TS-preserving Chern insulators (IQH/ChI); green lines correspond to trivial correlated insulators (CI); blue lines correspond to charge density waves (CDW); yellow lines correspond to TS-broken Chern insulators (SBCI); and orange lines correspond to (both TS-preserving and TS-broken) fractional Chern insulators (FCI). The detailed definitions of these states can be found in Table 2. The red numbers 1–8 indicate the eight observed FCI states. Modified from Ref. Xie Y., Pierce A.T., Park J.M., Parker D.E., Khalaf E., Ledwith P., Cao Y., Lee S.H., Chen S., Forrester P.R., Watanabe K., Taniguchi T., Vishwanath A., Jarillo-Herrero P., Yacoby A. (2021b). Fractional Chern insulators in magic-angle twisted bilayer graphene. *Nature* 600(7889):439–443. doi: 10.1038/s41586-021-04002-3.

magnetic field, here the Berry curvature stems from the zero-field topological band of TBG-hBN and the role of the magnetic field is merely to redistribute Berry curvature. Once the Berry curvature can be flattened by other effects, the magnetic field will probably become unnecessary and these $\bar{\nu} = 1/3$ and $\bar{\nu} = 2/3$ FCIs are expected to survive at zero field. Indeed, zero-field $\bar{\nu} = 1/3$ FCIs in TBG-hBN were first numerically predicted at weaker $w_1 = 90$ meV (Abouelkomsan et al., 2020), where the Berry curvature is flatter. Alternatively, a reduction of w_0/w_1 or slightly increasing the twist angle can also improve the band geometry (Parker et al., 2021).

Apart from the weak-field FCI states 1 and 2, additional FCIs were also observed in TBG-hBN away from $3 < \nu < 4$ at slightly stronger magnetic fields, including TS-preserving states [state 6 with $(t, s) = (-13/5, -2/5)$ and state 7 with $(t, s) = (-4/3, -5/3)$] and TS-broken states [state 3 with $(t, s) = (-8/5, 11/10)$ and state 4 with $(t, s) = (-7/3, 2/9)$]. More intriguingly, there are also FCI states with coprime denominators of t and s , like state 5 with $(t, s) = (-5/2, -1/5)$ and state 8 with $(t, s) = (-1/2, -8/3)$, which are neither simple TS-preserving nor TS-broken states. These exotic FCIs may originate from complex interplay between the multicomponent nature of TBG and spatial symmetry.

FCIs in cold-atom systems

Beside solid-state moiré systems, the high microscopic control and precision that are achievable in ultracold atoms make them also among the most promising candidates to realize rich correlated physics. In fact, there is a long-standing interest to realize the FQHE via cold atoms. The key task is to achieve a tight-binding model with complex hopping. Theoretical works along this direction have proposed several schemes, such as dipole systems (Weber et al., 2022; Yao et al., 2012) and bosons in optical flux lattice (Cooper, 2011; Cooper and Moessner, 2012; Cooper and Dalibard, 2013; Sterdyniak et al., 2015), and predicted FCIs therein. In particular, tremendous effort is made to study onsite-interacting bosons confined in a square optical lattice penetrated by a uniform effective magnetic field. This system is described by the 2D Harper-Hofstadter-Hubbard (HHH) Hamiltonian

$$H = -J \sum_{m,n} \left(a_{m,n+1}^\dagger a_{m,n} + e^{i2\pi\phi n} a_{m+1,n}^\dagger a_{m,n} + \text{H.c.} \right) + \frac{U}{2} \sum_{m,n} \hat{n}_{m,n} (\hat{n}_{m,n} - 1), \quad (27)$$

where J is the nearest-neighboring hopping strength, $a_{m,n}^\dagger(a_{m,n})$ creates (annihilates) a boson on the lattice site (m, n) , ϕ is the effective magnetic flux through each elementary square of the lattice, U is the magnitude of onsite repulsion, and $\hat{n}_{m,n} = a_{m,n}^\dagger a_{m,n}$ is the occupation number operator on site (m, n) . A plethora of numerical works find bosonic Abelian and non-Abelian FCIs as ground states of the HHH model at rational flux density $\phi \leq 1/3$ when the interaction is sufficiently strong and the lowest band is partially filled (Palmer and Jaksch, 2006; Sørensen et al., 2005; Hafezi et al., 2007; Hormozi et al., 2012; Gerster et al., 2017; Möller and Cooper, 2015; Hudomal et al., 2019; Palm et al., 2021; Boesl et al., 2022). The introduction of longer-range hopping and reduction of flux density may further stabilize these states. Fine-tuned exponentially decaying hopping can even perfectly flatten the lowest band and support model FCIs as the zero-energy ground states (Kapit and Mueller, 2010; Liu et al., 2013b).

The FCI states found in the HHH model can be prepared quasi-adiabatically, that is, one begins with a trivial state with low entropy, then slowly ramps the system to the desired final state (Popp et al., 2004; Grusdt et al., 2014; Barkeshli et al., 2015; He et al., 2017; Motruk and Pollmann, 2017; Palm et al., 2021). This protocol relies on continuous phase transitions between FCIs and other competing phases like CDW and superfluid. While dissipation is often thought of being harmful to the success of state preparation, some protocols suggest using special dissipative mechanism to pumping bosons from higher bands to the lowest band to make the state closer to FCIs (Liu et al., 2021b).

Theoretical works are further encouraged by the rapid development of experimental techniques on artificial gauge field and quantum gas microscope, which make the HHH Hamiltonian a paradigmatic model that has been realized in cold-atom experiments. Once bosons are trapped in an optical lattice, the effective magnetic field can be achieved by generating an artificial gauge field through lattice shaking techniques (Aidelsburger et al., 2013; Miyake et al., 2013). The nontrivial band topology in the HHH model has been confirmed by measuring the transverse deflection of the atomic cloud in response to an optical gradient (Aidelsburger et al., 2015). Further, the model has been pushed into the strong-interaction regime (Eric Tai et al., 2017), such that FCIs of ultracold atomic gases may potentially be within reach in the not too distant future.

Motivated by the encouraging theoretical and experimental progress, recent research focuses on how to detect FCI states once they are ready in cold-atom systems. In particular, such detection should be experimentally feasible and valid for those few-particle settings limited by the current technology. One way of detection is to probe the Hall conductance. However, because the transport measurements akin to those in solid state systems cannot be straightforwardly adopted into the cold-atom setting, alternative schemes have to be designed to extract Hall conductance. There have been several protocols on this aspect. One can apply a weak external force to the atomic cloud and track its center of mass drift (Repellin et al., 2020a; Motruk and Na, 2020). It is also possible to evaluate Hall conductance using interferometric protocols (Grusdt et al., 2016), randomized measurement scheme (Cian et al., 2021), or through circular-dichroic measurement (Tran et al., 2017; Repellin and Goldman, 2019). Apart from Hall conductance measurements, other promising schemes include probing fractionalized quasiholes through density measurement (Mantas Raciūnas et al., 2018; Umucalılar, 2018; Macaluso et al., 2020; Wang et al., 2022) and detecting chiral edge excitation (Kjäll and Moore, 2012; Dong et al., 2018). All of these proposals have been examined by numerical simulations in small cold-atom systems. Yet, it remains unclear which protocol is the most experimentally feasible before FCIs of cold atoms really turn to reality.

Conclusion

In this chapter, we have presented an introduction to fractional Chern insulators in topological flat bands. While FCIs share key features with conventional FQH states, the significant discrepancies between a Chern band and a Landau level make FCIs an ideal stage to realize the FQH physics under more general experimental conditions, to explore in the pursuit for qualitatively new topologically ordered states, and for unveiling the profound interplay between interaction, topology and geometry. Although it is impossible to provide a fully comprehensive account of the entire field here, we hope that our introduction has demonstrated the major methodology that has been used to understand FCIs and the new research trends which are emerging recently in this field.

The enthusiasm of studying FCIs has lasted over the past decade, and is now gaining renewed and extended interest due to their direct relevance in moiré materials. We would like to close this chapter by listing several directions which in our opinion are important for the development of this field in near future.

- *Exploring new platforms.* The recent trend of studying FCIs in moiré materials has clearly demonstrated the intimate relation between FCI and material science. Searching for new solid-state platforms that can host FCIs will significantly stimulate further development of this field. The research in this direction will need contributions from material calculations via, for instance, density functional theory. In fact, progress is already being made in this direction. In addition to more graphene based materials (Park et al., 2020; Rademaker et al., 2020; Chen et al., 2021), moiré systems built on transition metal dichalcogenides (TMD) are found to support topological flat bands (Wu et al., 2019; Pan et al., 2020; Li et al., 2021b; Zhang et al., 2021; Devakul et al., 2021; Pan et al., 2021; Zhou et al., 2022). Excitingly, a few numerical works have identified FCIs in twisted TMD homobilayers, like twisted bilayer MoTe_2 (Li et al., 2021a) and WSe_2 (Crépeel and Fu, 2022). It requires more effort to thoroughly investigate FCI states and their competing phases in these new materials. These theoretical explorations will be greatly helpful to accelerate the experimental realization of zero-field FCIs.
- *Experimental realization of high-temperature zero-field FCIs.* Despite of the encouraging experimental observation of FCI states in TBG-hBN at weak magnetic fields down to ~ 5 T (Xie et al., 2021b), how to stabilize these states at further reduced fields remains a crucial challenge for really achieving zero-field FCIs. Theoretical works have suggested to probe TBG-hBN at twist angles above the magic angle, which could improve the band geometry such that the magnetic field might become unnecessary (Parker et al., 2021). Alternatively, one can also try other materials like twisted bilayer TMD. These proposals should be examined by experiments, then the optimal setups which facilitate the realization of zero-field FCIs the most can be selected. Moreover, apart from the compressibility measurement used in current experiments, transport features, which directly show the characterizing Hall conductance plateaus, is in an ideal situation a preferable method to identify FCIs in the future.

In addition to the static realization of zero-field FCIs, one may also consider the dynamic preparation of these states in periodically driven systems. Recently, there have been a series of works studying the photon-dressed band structure of moiré materials driven by an external laser light field (Topp et al., 2019; Katz et al., 2020; Vogl et al., 2020; Li et al., 2020; Rodriguez-Vega et al., 2020; Assi et al., 2021; Topp et al., 2021; Vogl et al., 2021; Benlakhrouy et al., 2022). Based on these Floquet band structures, numerical simulations have demonstrated the possibility of Floquet FCIs (Grushin et al., 2014; Anisimovas et al., 2015) in light-driven TBG (Hu and Liu, 2022).

The energy gaps of the observed $\bar{\nu} = 1/3$ FCIs in TBG-hBN are about 0.6 K (Xie et al., 2021b), which are still close to that of the conventional Laughlin state in 2DEGs. Considering the expectation that FCIs can in principle exist at much higher temperature than conventional FQH states, it is definitely worthy of seeking a way to further increase the gap.

- *Searching and understanding new states.* With more theoretical and experimental explorations in various platforms, we should pay special attention on searching and understanding new states. Clearly, non-Abelian FCI states are still absent in experimental observation. In fact, it is difficult to get them even in numerical simulations, where multi-body interactions are often required (Wang et al., 2012b; Andrei Bernevig and Regnault, 2012; Wu et al., 2012a; Sterdyniak et al., 2013; Behrmann et al., 2016). Considering the potential application of non-Abelian anyons in topological quantum computation, it is a challenging albeit urgent task to find schemes that can provide non-Abelian FCIs by realistic two-body interactions.

The valley and spin degrees of freedom in moiré systems make it interesting to probe novel multicomponent FCI states. On the other hand, the symmetry-broken and other exotic FCI states (Table 2) found in the recent TBG-hBN experiment (Xie et al., 2021b) fall beyond the scope of conventional translational-symmetry-preserving FCIs. Apparently they have no analog in continuum FQH states. More theoretical and experimental effort is needed to understand these enigmatic states. Crucial open questions include: (i) Can these states survive at zero magnetic field? (ii) Can numerical simulations probe these states and extract their topological orders? (iii) Can experiments further identify the nature of these states, for example, their quasihole charges?

Motivated by seeking solutions of the questions above, we are convinced that the study of FCIs will remain an active field providing exciting and beautiful new physics.

Abstract

The unitary correspondence between Quantum Hall states in higher Landau levels and states in the lowest Landau level is discussed together with the resulting transformation formulas for particle densities and interaction potentials. This correspondence leads in particular to a representation of states in arbitrary Landau levels in terms of holomorphic functions. Some important special Quantum Hall states in higher Landau levels are also briefly discussed.

Key points

- Describe the emergence of Landau levels from the quantized two-dimensional motion of charged particles in a perpendicular magnetic field.
- Introduce non-commutative guiding center and cyclotron variables and the associated two commuting harmonic oscillators.
- Discuss the description of states in higher Landau levels in terms of holomorphic wave functions in the lowest Landau level.
- Derive formulas that express particle densities and interaction potentials in an arbitrary Landau level in terms of corresponding quantities in the lowest Landau level.
- Discuss briefly Laughlin states in higher Landau levels and recent investigations of states with filling factor $5/2$.

Notations

- ℓ_B Magnetic length
- LLL Lowest Landau level (single particle)
- LLL^N Lowest Landau level (N particles)
- nLL n -th Landau level (single particle)
- nLL^N n -th Landau level (N particles)
- Π_0 Projector on LLL
- Π_n Projector on nLL

Introduction

The quantum states of charged particles moving in a plane orthogonal to a homogeneous magnetic field are naturally grouped into Landau levels which correspond to quantization of the cyclotron motion of the particles in the magnetic field. The interplay of this motion with external electric fields and impurities as well as Coulomb interactions between the particles is the subject of Quantum Hall Physics which has developed into a major subfield of condensed matter physics since the discovery of the integer and fractional Quantum Hall Effects in Klitzing et al. (1980) and Störmer et al. (1982) respectively. These developments are extensively discussed in many monographs and review articles, see, e.g., (Chakraborty and Pietiläinen, 1988; Chakraborty and Pietiläinen, 1995; Goerbig, 2009; Fradkin, 2013; Laughlin, 1987, 1999; Prange and Girvin, 1987; Störmer et al., 1999; Goerbig and Lederer, 2006; Greiter, 2011; Jain, 2007; Tong, 2016). The present chapter focuses on one particular theoretical aspect, namely the relations between some basic properties of Quantum Hall states in different Landau levels.

In strong magnetic fields the lowest Landau level, corresponding to the smallest of the discrete values for the cyclotron radius, plays a special role. The fractional quantum Hall effect was first discovered in strongly correlated states within this level and the celebrated Laughlin wave function (Laughlin, 1983), describing a quantum liquid at filling factor $1/3$ (more generally $1/q$ with small odd values of q), turned out to be very successful in describing ground state properties as well as excitations.

An important mathematical feature of wave functions in the lowest Landau level is the fact that they form a Bargmann space of *holomorphic* functions when the position coordinates are expressed as complex numbers in the symmetric gauge. The holomorphy has been used for derivations of some basic properties of the states, for examples bounds on the local particle density (Lieb et al., 2018; Lieb et al., 2019). Wave functions in higher Landau levels, on the other hand, involve also powers of the complex conjugate position variables in the standard representation and at first sight it might appear that the advantage of holomorphic representations gets lost.

It was, however, noted early (MacDonald, 1984) that, due to a unitary correspondence between states in different Landau levels, wave functions in higher Landau levels can also be represented by holomorphic functions. In particular, there are Laughlin states in any Landau level. The physical picture behind this correspondence is based on the fact that the position variable has a natural decomposition into two sets of non-commutative variables, one associated with the cyclotron motion and the other with the *guiding centers* around which the cyclotron motion takes place. Mathematically, these correspond to two sets of mutually commuting harmonic oscillators. For a given Landau level, the cyclotron motion can be thought of as fixed, while the physics takes place in the guiding center degrees of freedom where holomorphic wave functions appear naturally.

In this chapter the mathematical implementation of this idea is presented in two versions, one employing ladder operators and another one based on coherent states. Each brings different aspects of the unitary correspondence between states in higher Landau levels with those in the lowest Landau level into focus. Furthermore we derive formulas that relate effective potentials in higher Landau levels to their counterparts in the lowest Landau level.

In the last section we discuss some important special states in higher Landau levels and their relation to states in the lowest Landau level.

The magnetic Hamiltonian and its Eigenfunctions

The Landau levels

The magnetic Hamiltonian of a single spinless (or spin-polarized) particle of charge q and effective mass m^* , moving in a plane with position variables $\mathbf{r} = (x, y)$, is

$$H = \frac{1}{2m^*} (\pi_x^2 + \pi_y^2) \quad (1)$$

where

$$\boldsymbol{\pi} = (\pi_x, \pi_y) = \mathbf{p} - q\mathbf{A} \quad (2)$$

is the gauge invariant kinetic momentum with

$$\mathbf{p} = -i\hbar(\partial_x, \partial_y) \quad (3)$$

the canonical momentum and $\mathbf{A}$ the magnetic vector potential. We assume a homogeneous magnetic field of strength B perpendicular to the plane and choose the symmetric gauge

$$\mathbf{A} = \frac{B}{2} (-y, x). \quad (4)$$

Moreover, we choose units and signs such that $|q| = 1$, $qB \equiv B > 0$, $\hbar = 1$ and $m^* = 1$. Then

$$\pi_x = -i\partial_x + \frac{1}{2}By, \quad \pi_y = -i\partial_y - \frac{1}{2}Bx \quad (5)$$

and the kinetic momentum components satisfy the canonical commutation relations (CCR)

$$[\pi_x, \pi_y] = i\ell_B^{-2} \quad (6)$$

with

$$\ell_B = B^{-1/2} \quad (7)$$

the magnetic length.

In terms of the creation and annihilation operators

$$a^\dagger = \frac{\ell_B}{\sqrt{2}} (-\pi_y - i\pi_x), \quad a = \frac{\ell_B}{\sqrt{2}} (-\pi_y + i\pi_x) \quad (8)$$

with $[a, a^\dagger] = 1$ one can write (1) as

$$H = 2B \left(a^\dagger a + \frac{1}{2} \right) \quad (9)$$

which is the Hamiltonian of a harmonic oscillator with eigenvalues

$$\varepsilon_n = \left(n + \frac{1}{2} \right) 2B, n = 0, 1, \dots \quad (10)$$

The Gaussian

$$\varphi_0(\mathbf{r}) = \frac{1}{\sqrt{\pi}} e^{-(x^2+y^2)/4\ell_B^2} \quad (11)$$

with $a\varphi_0 = 0$ is a ground state for H with energy $\varepsilon_0 = B$.

The discrete energy values (10) result from the quantization of the classical *cyclotron motion* of a charged particle around *guiding centers* as discussed below. Every energy eigenvalue is infinitely degenerate due to the different possible positions of the guiding centers. The degeneracy per unit area is $(2\pi\ell_B^2)^{-1}$.

The eigenspace in $L^2(\mathbb{R}^2)$ to the eigenvalue ε_n is called the *n-th Landau level* and denoted by nLL . The *lowest Landau level*, corresponding to $n = 0$ will be denoted by LLL . The corresponding fermionic spaces for N electrons, denoted by nLL^N and LLL^N respectively, are the antisymmetric tensor powers

$$LLL^N = LLL^{\otimes_a N}, \quad nLL^N = nLL^{\otimes_a N}. \quad (12)$$

For bosons the antisymmetric tensor product is replaced by the symmetric one; this is e.g. relevant for cold atomic gases in rapid rotation, where the rotational velocity takes over the role of the magnetic vector potential (Cooper, 2008).

The *filling factor* ν in a given Landau level is by definition the ratio of the particle density in that level to the degeneracy $(2\pi\ell_B^2)^{-1}$ per unit area. In a sample with area A a completely filled Landau level of fermions (filling factor $\nu = 1$) thus contains $N = (2\pi\ell_B^2)^{-1}A$ particles.

Remark. In the whole chapter, with the exception of the last Section 8.2, we focus on the orbital motion of the charged particles, ignoring spin and the accompanying Zeeman energy $\sum_i g^* \mu_B \mathbf{B} \cdot \mathbf{S}_i$ (with $\mathbf{S}_i$ the spin operator for particle i , $\mathbf{B}$ the magnetic field, μ_B the Bohr magneton and g^* the effective Landé g-factor). This is justified if the particles are either spinless, or their spin is fully polarized due to a strong magnetic field. Moreover, in semiconductors the Zeeman energy is typically much smaller than the gap between Landau levels because the effective g-factor is small. See, e.g., (Tong, 2016, p. 16).

The two oscillators

Quantum mechanically the dynamics of the guiding centers is described by another harmonic oscillator commuting with the cyclotron oscillator (1). While the latter determines the Landau energy spectrum (10), the quantization of the guiding center oscillator parametrizes the degeneracy creating a natural basis of states in each Landau level.

One arrives at this picture by splitting the (gauge invariant) position operator $\mathbf{r}$ into a guiding center part $\mathbf{R}$ and the cyclotron part

$$\tilde{\mathbf{R}} = \ell_B^2 \mathbf{n} \times \boldsymbol{\pi}, \quad (13)$$

with $\mathbf{n}$ the unit normal vector to the plane. Both $\mathbf{R}$ and $\tilde{\mathbf{R}}$ are gauge invariant and they commute with each other. On the other hand the two components (R_x, R_y) of $\mathbf{R}$ do not commute and likewise for the components of $\tilde{\mathbf{R}}$. More precisely, we have

$$\mathbf{r} = \mathbf{R} + \tilde{\mathbf{R}} \quad (14)$$

with

$$R_x = x + \ell_B^2 \pi_y = \frac{1}{2} x - i\ell_B^2 \partial_y, \quad R_y = y - \ell_B^2 \pi_x = \frac{1}{2} y + i\ell_B^2 \partial_x, \quad (15)$$

$$\tilde{R}_x = -\ell_B^2 \pi_y = \frac{1}{2}x + i\ell_B^2 \partial_y, \quad \tilde{R}_y = \ell_B^2 \pi_x = \frac{1}{2}y - i\ell_B^2 \partial_x \quad (16)$$

and the commutation relations

$$[\mathbf{R}, \tilde{\mathbf{R}}] = \mathbf{0}, \quad [R_x, R_y] = -i\ell_B^2, \quad [\tilde{R}_x, \tilde{R}_y] = i\ell_B^2. \quad (17)$$

The creation and annihilation operators for $\tilde{\mathbf{R}}$ are the same as (8), namely

$$a^\dagger = \frac{1}{\sqrt{2\ell_B}} (\tilde{R}_x - i\tilde{R}_y), \quad a = \frac{1}{\sqrt{2\ell_B}} (\tilde{R}_x + i\tilde{R}_y). \quad (18)$$

Those for the guiding centers, on the other hand, are

$$b^\dagger = \frac{1}{\sqrt{2\ell_B}} (R_x + iR_y), \quad b = \frac{1}{\sqrt{2\ell_B}} (R_x - iR_y). \quad (19)$$

with $[b, b^\dagger] = 1$ and $[a^\dagger, b^\dagger] = 0$. Note the different signs compared to (18) due to the different signs in (17).

Complex notation

The two-dimensional configuration space $\mathbb{R}^2$ can be identified with the complex plane $\mathbb{C}$. Defining complex coordinates and derivatives by

$$z = x + iy, \quad \bar{z} = x - iy, \quad \partial_z = \frac{1}{2}(\partial_x - i\partial_y), \quad \partial_{\bar{z}} = \frac{1}{2}(\partial_x + i\partial_y) \quad (20)$$

we can write

$$a^\dagger = \frac{1}{\sqrt{2\ell_B}} \left(\frac{1}{2}\bar{z} - 2\ell_B^2 \partial_z \right), \quad a = \frac{1}{\sqrt{2\ell_B}} \left(\frac{1}{2}z + 2\ell_B^2 \partial_{\bar{z}} \right). \quad (21)$$

Choosing units so that $B = 2$, or equivalently, defining $z = \frac{1}{\sqrt{2\ell_B}}(x + iy)$, this simplifies to

$$a^\dagger = \frac{1}{2}\bar{z} - \partial_z, \quad a = \frac{1}{2}z + \partial_{\bar{z}}. \quad (22)$$

Also, the gaussian factor $e^{-(|x|^2+|y|^2)/4\ell_B^2}$ becomes $e^{-|z|^2/2}$. We note that besides the standard definition $z = x + iy$, other complexifications of $\mathbb{R}^2$ are possible and can be useful, as stressed in Haldane (2018).

For computations it is often convenient to use instead of (22) the operators $\hat{a}^\dagger, \hat{a}$ which act only on the pre-factors to the gaussian and are defined by

$$a^\dagger [f(z, \bar{z}) e^{-|z|^2/2}] = [\hat{a}^\dagger f(z, \bar{z})] e^{-|z|^2/2}. \quad (23)$$

These are

$$\hat{a}^\dagger = \bar{z} - \partial_z, \quad \hat{a} = \partial_{\bar{z}}. \quad (24)$$

In the sequel we shall generally use the hat $\hat{\cdot}$ on operators and functions to indicate that gaussian normalization factors are dropped from the notation.

The creation and annihilation operators for the guiding center oscillator are in complex notation

$$b^\dagger = \frac{1}{\sqrt{2\ell_B}} \left(\frac{1}{2}z - 2\ell_B^2 \partial_{\bar{z}} \right), \quad b = \frac{1}{\sqrt{2\ell_B}} \left(\frac{1}{2}\bar{z} + 2\ell_B^2 \partial_z \right). \quad (25)$$

For $B = 2$

$$b^\dagger = \frac{1}{2}z - \partial_{\bar{z}}, \quad b = \frac{1}{2}\bar{z} + \partial_z \quad (26)$$

and

$$\hat{b}^\dagger = z - \partial_{\bar{z}}, \quad \hat{b} = \partial_z. \quad (27)$$

The splitting (14) corresponds to

$$(z, \bar{z}) = (b^\dagger, b) + (a, a^\dagger). \quad (28)$$

While the operators $a^\dagger, a$ increase or decrease the Landau level index, the operators $b^\dagger, b$ leave each Landau level invariant. Pictorially speaking we can say that operators $a^\dagger$ associated with the cyclotron oscillator are ladder operators moving states “vertically” on the energy scale, while the ladder operators $b^\dagger$ associated with the guiding center oscillator move states “horizontally”, keeping the energy fixed.

Eigenfunctions

With the gaussian $\varphi_{0,0} := \varphi_0$ (11) as the common, normalized lowest energy state for the two oscillators the states

$$\varphi_{n,m} = \frac{1}{\sqrt{n!m!}} (a^\dagger)^n (b^\dagger)^m \varphi_{0,0} = \frac{1}{\sqrt{n!m!}} (b^\dagger)^m (a^\dagger)^n \varphi_{0,0}, \quad n, m = 0, 1, \dots \quad (29)$$

form a basis of eigenstates of the Hamiltonian (1). For fixed n the states $\varphi_{n,m}$, $m = 0, 1, \dots$ generate the Hilbert space $n\text{LL}$ of the n 'th Landau level with $n = 0$ corresponding to the lowest Landau level LLL.

In complex coordinates the wave functions with $n = 0$ respectively $m = 0$, are

$$\varphi_{0,m}(\mathbf{r}) = \frac{1}{\sqrt{\pi m!}} z^m e^{-|z|^2/2}, \quad \varphi_{n,0}(\mathbf{r}) = \frac{1}{\sqrt{\pi n!}} \bar{z}^n e^{-|z|^2/2}. \quad (30)$$

More generally, one can write

$$\varphi_{n,m}(\mathbf{r}) = \frac{1}{\sqrt{\pi n!m!}} [(z - \partial_{\bar{z}})^m \bar{z}^n] e^{-|z|^2/2} = \frac{1}{\sqrt{\pi n!m!}} [(\bar{z} - \partial_z)^n z^m] e^{-|z|^2/2}. \quad (31)$$

These functions can be written in polar coordinates in terms of associated Laguerre polynomials (Landau and Lifschitz, 1977; Gradshteyn and Ryzhik, 1994). They are simultaneous eigenfunctions of the Hamiltonian (1) and the angular momentum operator $\mathbf{L} = \mathbf{r} \times \mathbf{p}$ in the symmetric gauge. Its action on the pre-factor of the gaussian is

$$\hat{L} = z\partial_z - \bar{z}\partial_{\bar{z}} \quad (32)$$

with eigenvalues $M = m - n$, $m = 0, 1, \dots$ in the $n\text{LL}$. The operators $b^\dagger$ and b shift the angular momentum within each Landau level.

Factorization

The mutual commutativity of the two oscillators has an important consequence:

Lemma 2.1: (Factorization). If A is a function of $a^\dagger$, a and B of $b^\dagger$, b , then

$$\langle \varphi_{n',m'} | AB | \varphi_{n,m} \rangle = \langle \varphi_{n',0} | A | \varphi_{n,0} \rangle \langle \varphi_{0,m'} | B | \varphi_{0,m} \rangle. \quad (33)$$

The proof follows from the fact that the two commuting harmonic oscillators (8) and (19) can be represented, in a unitarily equivalent way, in the tensor product of two spaces with basis vectors $\varphi_{n,0}$ and $\varphi_{0,m}$ respectively. In this representation $\varphi_{n,m} \simeq \varphi_{n,0} \otimes \varphi_{0,m}$ and the operators A and B act independently on each of the tensor factors. (Alternatively, one can choose A , B to be polynomials in the creation and annihilation operators and use the CCR to prove (33) directly.) Note, however, that in the representation (31) the functions $\varphi_{n,m}(z, \bar{z})$ are not simply products of the functions $\varphi_{n,0}(z)$ and $\varphi_{0,m}(\bar{z})$. Indeed, the variables z and $\bar{z}$ do not act independently in the tensor factors because they involve sums of $a^{\#}$'s and $b^{\#}$'s, cf. Eq. (28). The lemma, however, is in accord with the intuitive picture stressed in Haldane (2013) that in a given Landau level all the non-trivial structure is in the guiding center degrees of freedom while the cyclotron motion just produces a decoration by a fixed factor in matrix elements.

The lowest Landau level as a Bargmann space of holomorphic functions

Wave functions ψ in the lowest Landau level LLL are characterized by the equation

$$a\psi = 0 \quad (34)$$

which by (24) means that

$$\psi(\mathbf{r}) = f(z) e^{-|z|^2/2} \quad (35)$$

with f satisfying the Cauchy-Riemann equation $\partial_{\bar{z}} f = 0$, i.e., f is a *holomorphic* function of z . Holomorphic functions that are square integrable on $\mathbb{R}^2$ with respect to the Lebesgue measure with the gaussian weight factor $e^{-|z|^2}$ form a *Bargmann space* (Bargmann, 1961).

In the same way, N -particle fermionic wave functions in LLL^N have the form

$$\Psi(\mathbf{r}_1, \dots, \mathbf{r}_N) = F(z_1, \dots, z_N) e^{-(|z_1|^2 + \dots + |z_N|^2)/2} \quad (36)$$

with a holomorphic, antisymmetric function F of the N variables $z_1, \dots, z_N$.

In the sequel we shall show that representations of states by holomorphic functions are not limited to the lowest Landau level.

Unitary maps between Landau levels

The structure of the eigenfunctions (29) with the mutually commuting sets of creation and annihilation operators $a^\#$ and $b^\#$ for the two oscillators leads immediately to a unitary correspondence $n\text{LL} \leftrightarrow \text{LLL}$. In fact, the operator

$$U_n = (n!)^{-1/2} a^n \quad \text{restricted to } n\text{LL} \quad (37)$$

maps $\varphi_{n,m} \mapsto \varphi_{0,m}$ because a commutes with $b^\dagger$, and the inverse

$$U_n^{-1} = (n!)^{-1/2} (a^\dagger)^n \quad \text{restricted to LLL} \quad (38)$$

takes $\varphi_{0,m} \mapsto \varphi_{n,m}$. Hence U_n is a unitary map $n\text{LL} \rightarrow \text{LL}$.

The wave functions in $n\text{LL}$ are by (31) polynomials in $\bar{z}$ of order n with coefficients that are holomorphic functions of z . Using the representations (24) for the creation and annihilation operators we conclude that the following holds:

Proposition 3.1: (Unitary map between $n\text{LL}$ and LLL)

Let $\psi_n \in n\text{LL}$ have wave function

$$\psi_n(\mathbf{r}) = \sum_{k=0}^n \bar{z}^k f_k(z) e^{-|z|^2/2}, \quad (39)$$

with f_k holomorphic for $k = 0, \dots, n$. Then $\psi_0 = U_n \psi_n \in \text{LLL}$ has the wave-function

$$\psi_0(\mathbf{r}) = \sqrt{n!} f_n(z) e^{-|z|^2/2}. \quad (40)$$

Conversely, the wave function of $\psi_n = U_n^{-1} \psi_0 \in n\text{LL}$ is

$$\begin{aligned} \psi_n(\mathbf{r}) &= [(\bar{z} - \partial_z)^n f_n(z)] e^{-|z|^2/2} \\ &= \left[\bar{z}^n f_n(z) + \sum_{k=1}^n (-1)^k \binom{n}{k} \bar{z}^{n-k} \partial^k f_n(z) \right] e^{-|z|^2/2}. \end{aligned} \quad (41)$$

Note that Eq. (41) implies in particular that the holomorphic factor $f_n(z)$ to the highest power n of $\bar{z}$ determines uniquely the factors to the lower powers $\bar{z}^k$:

$$f_k(z) = (-1)^{n-k} \binom{n}{k} f_n^{(n-k)}(z). \quad (42)$$

A wave function in $n\text{LL}$ is thus *completely fixed by the holomorphic function f_n and the Landau level index n* .

These considerations lead also to a formula for projecting functions into the lowest Landau level:

Proposition 3.2: (LLL projection).

Let ϕ be a state in $\oplus_{k=0}^n k\text{LL}$ with wave function

$$\phi(\mathbf{r}) = \sum_{k=0}^n \bar{z}^k g_k(z) e^{-|z|^2/2} \quad (43)$$

with holomorphic functions g_k . It's orthogonal projection into LLL is

$$\Pi_0 \phi(z) = \sum_{k=0}^n \partial^k g_k(z) e^{-|z|^2/2}. \quad (44)$$

This is known as the recipe “move all $\bar{z}$ factors to the left and replace them by derivatives in z ”, see e.g. (Jain, 2007).

Proof. The previous considerations lead by induction to a splitting of the state (43) into its components in the different $k\text{LL}$, $k = 0, \dots, n$: Start with a wave function as in (43). It's component ψ_n in the $n\text{LL}$ is given by (41) with $f_n := g_n$ and f_k for $0 \leq k \leq n-1$ defined by (42). The difference $\tilde{\phi} = \phi - \psi_n$ is now in $\oplus_{k=0}^{n-1} k\text{LL}$ and we can repeat the procedure with n replaced by $n-1$, ϕ by $\tilde{\phi}$ etc. until we obtain the splitting $\phi = \sum_{k=0}^n \psi_k$ with $\psi_k \in k\text{LL}$. By induction over n , using that $\sum_{k=0}^n \binom{n}{k} (-1)^k = (1-1)^n = 0$, this procedure implies (44).

Many body states and ℓ -particle densities

The considerations of the previous sections carry in a straightforward manner over to many-body states in symmetric or anti-symmetric tensor powers $n\text{LL}^N \equiv n\text{LL}^{\otimes n, \text{as}, N}$ of single-particle states by applying the single-particle formulas to each tensor factor.

Let Ψ_n be a state in $n\text{LL}^N$ with wave function

$$\Psi_n(\mathbf{r}_1, \dots, \mathbf{r}_N) = \hat{\Psi}_n(\mathbf{r}_1, \dots, \mathbf{r}_N) e^{-(|z_1|^2 + \dots + |z_N|^2)/2}. \quad (45)$$

Expanding in powers of $\bar{z}_i$ we can write

$$\hat{\Psi}_n(\mathbf{r}_1, \dots, \mathbf{r}_N) = \prod_{i=1}^N \bar{z}_i^n f_n(z_1, \dots, z_N) + \sum \prod_{i=1}^N \bar{z}_i^{k_i} f_{k_1, \dots, k_N}(z_1, \dots, z_N). \quad (46)$$

The sum is here over N -tuples $(k_1, \dots, k_N)$ such that $k_i < n$ for at least one i . The functions f_n and $f_{k_1, \dots, k_N}$ are holomorphic and the latter ones are, in fact, derivatives of f_n , cf. (42).

Consider now the state $\Psi_0 = \mathcal{U}_{N,n} \Psi_n$ in LLL^N where

$$\mathcal{U}_{N,n} = U_n \otimes \dots \otimes U_n \quad \text{with } U_n \text{ defined by (37)}. \quad (47)$$

Its wave function is

$$\Psi_0(\mathbf{r}_1, \dots, \mathbf{r}_N) = \hat{\Psi}_0(z_1, \dots, z_N) e^{-(|z_1|^2 + \dots + |z_N|^2)/2} \quad (48)$$

with the holomorphic function

$$\hat{\Psi}_0(z_1, \dots, z_N) = (n!)^{-N/2} \prod_{i=1}^N \partial_{\bar{z}_i}^n \hat{\Psi}_n(z_1, \bar{z}_1; \dots; z_N, \bar{z}_N) = (n!)^{N/2} f_n(z_1, \dots, z_N). \quad (49)$$

Now $\Psi_n = \mathcal{U}_{N,n}^{-1} \Psi_0$ so the wave function $\hat{\Psi}_n$ can by (38) and (24) be expressed in terms of the holomorphic function f_n :

$$\hat{\Psi}_n(z_1, \bar{z}_1; \dots; z_N, \bar{z}_N) = (n!)^{-N/2} \prod_{i=1}^N (\bar{z}_i - \partial_{\bar{z}_i})^n \hat{\Psi}_0(z_1, \dots, z_N) = \prod_{i=1}^N (\bar{z}_i - \partial_{\bar{z}_i})^n f_n(z_1, \dots, z_N). \quad (50)$$

Next we consider ℓ -particle densities, $\ell = 1, 2, \dots$, which for a general N -particle wave function Ψ are defined by

$$\rho_{\Psi}^{(\ell)}(\mathbf{r}_1, \dots, \mathbf{r}_{\ell}) = \binom{N}{\ell} \int_{\mathbb{R}^{2(N-\ell)}} |\Psi(\mathbf{r}_1 \dots \mathbf{r}_{\ell}; \mathbf{r}'_{\ell+1} \dots \mathbf{r}'_N)|^2 d\mathbf{r}'_{\ell+1} \dots d\mathbf{r}'_N. \quad (51)$$

Theorem 4.1: (Particle densities in the n -th Landau level)

The ℓ -particle densities of $\Psi_n \in n\text{LL}^N$ and $\Psi_0 = \mathcal{U}_{N,n} \Psi_n \in \text{LLL}^N$ are connected by

$$\rho_{\Psi_n}^{(\ell)}(\mathbf{r}_1, \dots, \mathbf{r}_{\ell}) = \prod_{i=1}^{\ell} L_n\left(-\frac{1}{4} \Delta_{\mathbf{r}_i}\right) \rho_{\Psi_0}^{(\ell)}(\mathbf{r}_1, \dots, \mathbf{r}_{\ell}) \quad (52)$$

where L_n is the n -th Laguerre polynomial

$$L_n(t) = \sum_{l=0}^n \binom{n}{l} \frac{(-t)^l}{l!}. \quad (53)$$

The proof is a simple consequence of the following Lemma:

Lemma 4.2: (Reshuffling differentiations)

Let f be a holomorphic function. Then

$$(n!)^{-1} [(\bar{z} - \partial_{\bar{z}})^n \overline{f(z)}] [(\bar{z} - \partial_{\bar{z}})^n f(z)] e^{-z\bar{z}} = L_n(-\partial_{\bar{z}} \partial_z) \left[\overline{f(z)} f(z) e^{-z\bar{z}} \right]. \quad (54)$$

Proof. This is a straightforward computation by induction over n , using the recursion relation for the Laguerre polynomials,

$$(n+1)L_{n+1}(u) = (2n+1)L_n(u) - nL_{n-1}(u) - uL_n(u). \quad (55)$$

To compute

$$\partial_{\bar{z}} \partial_z \left[[(\bar{z} - \partial_{\bar{z}})^n \overline{f(z)}] [(\bar{z} - \partial_{\bar{z}})^n f(z)] e^{-z\bar{z}} \right], \quad (56)$$

starting with $n = 0$ and $L_0 = 1$, one uses the commutation relations

$$\partial_{\bar{z}}(\bar{z} - \partial_z)^n = (\bar{z} - \partial_z)^n \partial_{\bar{z}} + n(\bar{z} - \partial_z)^{n-1}, \quad \partial_z(\bar{z} - \partial_z)^n = (\bar{z} - \partial_z)^n \partial_z, \quad (57)$$

and the fact that $\partial_{\bar{z}} f(z) = \partial_z \overline{f(z)} = 0$ for holomorphic f .

Theorem 4.1 follows by applying the Lemma to the first ℓ variables of Ψ_0 , noting that $\partial_z \partial_{\bar{z}} = \frac{1}{4} \Delta$.

Mapping Hamiltonians to the LLL

Consider an N -body Hamiltonian of the form

$$H_{V,w} = \sum_{i=1}^N \left[H^{(i)} + V(\mathbf{r}_i) \right] + \sum_{i < j} w(\mathbf{r}_i - \mathbf{r}_j) \quad (58)$$

where $H^{(i)}$ is the 1-particle Landau Hamiltonian (1) for particle i , V is an external potential, and w a translationally invariant two-body interaction potential.

A common situation in Quantum Hall physics is that the first $n-1$ Landau levels are filled with electrons and can be regarded as “inert” while the interesting phenomena take place in the tensor factor of the state in the n -th Landau level. The formulas of the last section, which establish a unitary correspondence between states and densities in different Landau levels, make it possible to reduce the study of the Hamiltonian in the n -th level to a unitarily equivalent Hamiltonian in the lowest Landau level where states are described by holomorphic wave functions. This reduction is accompanied by a transformation of the potentials V and w . The precise statement is as follows:

Theorem 5.1: (Effective Hamiltonians in different LL’s).

Let $H_{V,w}$ be given by (58) and define

$$H_{V,w}^{nLL} = \Pi_n^N H_{V,w} \Pi_n^N \quad (59)$$

where Π_n^N is the orthogonal projector from $L^2_{\text{asym}}(\mathbb{R}^{2N})$ to nLL^N . Then, for any n ,

$$H_{V,w}^{nLL} - n \cdot 2B\mathcal{N} \quad (60)$$

is unitarily equivalent to

$$H_{V^{(n)},w^{(n)}}^{LLL} = \Pi_0^N H_{V^{(n)},w^{(n)}} \Pi_0^N \quad (61)$$

with Π_0^N the projector onto the lowest Landau level LLL^N and the effective potentials

$$V^{(n)}(\mathbf{r}) = L_n \left(-\frac{1}{4} \Delta \right) V(\mathbf{r}) \quad (62)$$

$$w^{(n)}(\mathbf{r}) = L_n \left(-\frac{1}{4} \Delta \right)^2 w(\mathbf{r}) \quad (63)$$

where Δ is the Laplacian and L_n the Laguerre polynomial (53). More generally, one can consider interactions beyond the two-body case: For an ℓ particle interaction the $L_n \left(-\frac{1}{4} \Delta \right)^2$ in (63) is replaced by a product of $L_n \left(-\frac{1}{4} \Delta_i \right)$, $i = 1, \dots, \ell$.

Proof. The proof follows directly from a comparison of expectation values of $H_{V,w}^{nLL}$ in a state $\Psi_n \in nLL^N$ with the corresponding state $\Psi_0 = \mathcal{U}_{N,n}^{-1} \Psi_n \in LLL^N$, using the transformation formula (52) for one- and two-particle densities (more generally, ℓ -particle densities).

Remark. This is the basic result that allows to study interaction in higher LL’s in terms of effective interactions in the LLL. It can be found in different guises in a number of sources, in particular (Haldane, 2018; Chen and Biswas, 2020; Tong, 2016; Jain, 2007; MacDonald and Girvin, 1986; Ciftja and Quintanilla, 2010).

Another proof of Theorem 5.1

An alternative approach to (62) and (63) is based on the splitting (14) of the position variables in guiding centers and cyclotron motion and the factorization $\exp(i\mathbf{q} \cdot \mathbf{r}) = \exp(i\mathbf{q} \cdot \mathbf{R}) \exp(i\mathbf{q} \cdot \hat{\mathbf{R}})$. This factorization carries over to matrix elements by Lemma 2.1.

Lemma 5.2: (Plane waves projected in different Landau levels).

For any $\mathbf{q} \in \mathbb{R}^2$, identify $e^{i\mathbf{q} \cdot \mathbf{r}}$ with the corresponding multiplication operator on $L^2(\mathbb{R}^2)$, where $\mathbf{r}$ is the spatial variable. Let $\mathbf{R}$ be the guiding center operator defined in Section “The two oscillators”, Π_n the orthogonal projector on nLL and $U_n : nLL \rightarrow LLL$ the unitary map (37). Then, in the LLL,

$$U_n \Pi_n e^{i\mathbf{q} \cdot \mathbf{r}} \Pi_n U_n^{-1} = L_n \left(\frac{|\mathbf{q}|^2}{4} \right) e^{-\frac{|\mathbf{q}|^2}{8}} \Pi_0 e^{i\mathbf{q} \cdot \mathbf{R}} \Pi_0 = L_n \left(\frac{|\mathbf{q}|^2}{4} \right) \Pi_0 e^{i\mathbf{q} \cdot \mathbf{r}} \Pi_0 \quad (64)$$

with L_n the Laguerre polynomial (53).

The equality of the left-hand and the right-hand sides of (64) can be seen as a Fourier transformed version of (52) (with $\ell = 1$).

The proof of the Lemma is a simple computation using the commutation relations (17) and the Baker-Campbell-Hausdorff formula

$$e^{X+Y} = e^X e^Y e^{-\frac{1}{2}[X,Y]} \quad (65)$$

for operators such that $[X, [X, Y]] = [Y, [X, Y]] = 0$. The computation can be found in Rougerie and Yngvason (2020), p. 12 and also in Jain (2007) (proof of Theorem 3.2 in that reference) and in Goerbig and Lederer (2006). Eqs. (62) and (63) follow from (64) by the Fourier decompositions

$$V(\mathbf{r}) = \int_{\mathbb{R}^2} \hat{V}(\mathbf{q}) e^{i\mathbf{q} \cdot \mathbf{r}} d\mathbf{q} \quad (66)$$

and

$$w(\mathbf{r}_1 - \mathbf{r}_2) = \int_{\mathbb{R}^2} \hat{w}(\mathbf{q}) e^{i\mathbf{q} \cdot \mathbf{r}_1} e^{-i\mathbf{q} \cdot \mathbf{r}_2} d\mathbf{q} \quad (67)$$

using the Fourier representation of the Laplacian, $-\Delta = |\mathbf{q}|^2$.

Coherent state representations

The considerations so far, in particular the holomorphic representation of states in any Landau level via the formulas (40) and (41), are based on the use of the ladder operators $a^\#$ which connect higher Landau levels with the LLL. We now discuss an alternative approach which offers additional insights. It relies on a representation of states in n LL in terms of coherent states for the guiding center oscillator.

Coherent states

A coherent state in n LL with parameter $Z \in \mathbb{C}$ associated with the guiding center oscillator is defined in a standard way (Klauder and Skagerstam, 1985; Combescur and Robert, 2021) as

$$|Z, n\rangle = e^{(Zb^\dagger - \bar{Z}b)} \varphi_{n,0} = \sum_{m=0}^{\infty} \frac{Z^m}{\sqrt{m!}} \varphi_{n,m} e^{-|Z|^2/2}. \quad (68)$$

The overlap of two coherent states is

$$\langle Z, n | Z', n' \rangle = \delta_{n,n'} e^{(2\bar{Z}Z' - |Z|^2 - |Z'|^2)/2} = \delta_{n,n'} e^{-|Z - Z'|^2/2} e^{i\text{Im}(\bar{Z}Z')} \quad (69)$$

and

$$\int |Z, n\rangle \langle Z, n| \frac{d^2 Z}{\pi} = \sum_{m=0}^{\infty} |\varphi_{n,m}\rangle \langle \varphi_{n,m}| = \Pi_n \quad (70)$$

is the projector on n LL, where $d^2 Z := \frac{i}{2} dZ \wedge d\bar{Z}$ is the Lebesgue measure on the plane.

The coherent states lead directly to an interpretation of n LL as a Bargmann space of holomorphic functions of the coherent state variable Z : If $\psi \in n$ LL then

$$\hat{\Psi}(Z) := \langle \bar{Z}, n | \psi \rangle e^{|Z|^2/2} = \sum_{m=0}^{\infty} \langle \varphi_{n,m} | \psi \rangle \frac{Z^m}{\sqrt{m!}} \quad (71)$$

is analytic in Z and

$$\Psi(Z, \bar{Z}) = \hat{\Psi}(Z) e^{-|Z|^2/2} \quad (72)$$

has the same L^2 norm as ψ because of (70). Thus the map

$$U_n : \psi \mapsto \Psi \quad (73)$$

is isometric from the n LL to the LLL. From the definition it is clear that

$$U_n \varphi_{n,m} = \varphi_{0,m} \quad \text{and} \quad U_n |Z, n\rangle = |Z, 0\rangle \quad (74)$$

with the inverse

$$U_n^{-1} \varphi_{0,m} = \varphi_{n,m} \quad \text{and} \quad U_n^{-1} |Z, 0\rangle = |Z, n\rangle. \quad (75)$$

Thus U_n is identical to the unitary defined by ladder operators in (37) and (38). In particular the holomorphic function (71) is mathematically identical to the function $\hat{\psi}_0(z) = \sqrt{n!} f_n(z)$ in (40) if $\psi = \psi_n$ and Z is identified with the complex position variable $z = x + iy$. Note, however, that Z is associated with the (non-commutative) components of the guiding center operator $\mathbf{R}$ rather than the (commutative) position operator $\mathbf{r}$.

Remark. By the definition (71) Ψ depends linearly on ψ ; the alternative definition $\Psi(Z) = \langle \psi | Z, n \rangle$, that is used in some references, leads to an anti-unitary correspondence.

Integral kernels

The unitary map $\psi \mapsto \Psi$ defined by (71) can also be achieved using the integral kernel

$$G_n(Z, \bar{Z}; z, \bar{z}) = \frac{1}{\sqrt{\pi n!}} (z - Z)^n e^{-(|Z|^2 + |z|^2 - 2Z\bar{z})/2} = \frac{1}{\sqrt{\pi n!}} (z - Z)^n e^{-|z-Z|^2/2} e^{-i\text{Im}(\bar{z}Z)}. \quad (76)$$

Namely, we have

$$\Psi(Z, \bar{Z}) = \int G_n(Z, \bar{Z}; z, \bar{z}) \psi(z, \bar{z}) d^2 z. \quad (77)$$

The inverse map is given by

$$\psi(z, \bar{z}) = \int \bar{G}_n(z, \bar{z}; Z, \bar{Z}) \Psi(Z, \bar{Z}) d^2 Z \quad (78)$$

with

$$\bar{G}_n(z, \bar{z}; Z, \bar{Z}) = \frac{1}{\sqrt{\pi n!}} (\bar{z} - \bar{Z})^n e^{-(|Z|^2 + |z|^2 - 2Z\bar{z})/2} = \frac{1}{\sqrt{\pi n!}} (\bar{z} - \bar{Z})^n e^{-|z-Z|^2/2} e^{-i\text{Im}(z\bar{Z})}. \quad (79)$$

The (short) proof can be found in Rougerie and Yngvason (2020), p. 8 and also (with a slightly different notation) in Champel and Florens (2007), Eq. (34). See also Champel and Florens (2009) and Champel et al. (2008).

Note that G_n can be written as

$$g_n(z - Z) e^{-2i \text{Im}(\bar{z}Z)} \quad (80)$$

where g_n is essentially concentrated in a disc of radius $\sim \sqrt{n+1}$ and the factor is a phase factor. Recall also that the length unit is $\sqrt{2} \ell_B \sim B^{-1/2}$.

A further remark is that G_0 is the reproducing kernel for the Bargmann space, confirming again that in the LLL Ψ and ψ are the same function on $\mathbb{C}$ just with different names for the variables. The phase factor in G_n is essential for this to hold.

Recap of the different expressions for the unitary maps

In the previous sections we have displayed three equivalent ways to represent a state $\psi \in n$ LL by holomorphic functions in Bargmann space:

1. Apply the differential operator $\partial_{\bar{z}}$ n -times to the pre-factor of the Gaussian, cf. Eqs. (37) and (38). Equivalently: Expand the pre-factor in powers of $\bar{z}$ and keep only the highest power. The inverse mapping, $\text{LLL} \rightarrow n\text{LL}$, is achieved by applying the differential operator $(\bar{z} - \partial_z)^n$ to the analytic function representing the state in the LLL.
2. Take the scalar product $\langle \bar{Z}, n | \psi \rangle$ with a coherent state, cf. (71).
3. Use Eq. (77) with the integral kernel (76).

The three methods generalize in all cases to many body states in $n\text{LL}^N \equiv n\text{LL}^{\otimes_{s,s} N}$ by applying the prescriptions to each tensor factor.

Computationally the first method is usually the simplest, but the two others are sometimes more illuminating from the physics point of view since they bring the pivotal role of the guiding center variables into focus.

Some special states

Laughlin states

Consider an N -body Hamiltonian (58) with a rotationally symmetric interaction potential w but without an external potential. Its projection onto the LLL can be written as¹

$$H_w^{\text{LLL}} = \sum_{i < j} \sum_{m \geq 0} \langle \varphi_{0,m} | w | \varphi_{0,m} \rangle (| \varphi_{0,m} \rangle \langle \varphi_{0,m} |)_{ij}. \quad (81)$$

The matrix elements

$$w_m := \langle \varphi_{0,m} | w | \varphi_{0,m} \rangle = \frac{1}{\pi m!} \int_{\mathbb{R}^2} |w(\mathbf{r})| r^{2m} e^{-Br^2} d^2 \mathbf{r} \quad (82)$$

are usually called “Haldane pseudo-potentials”² cf. (Haldane, 1983). If the sum is truncated at $m = q-1$ for some natural number q then the *Laughlin wave function*

$$\Psi_N^{\text{Lau}}(z_1, \dots, z_N) = c_N \prod_{i < j} (z_i - z_j)^q e^{-\sum_{j=1}^N |z_j|^2/2} \quad (83)$$

is an exact ground state of (81) (L^2 -normalized by the constant in front).

The Laughlin state in LLL^N can also be written as

$$\Psi_N^{\text{Lau}} = c_N \prod_{i < j} (b_i - b_j)^q \varphi_{0,0}^{\otimes N} \quad (84)$$

and its counterpart in $n\text{LL}^N$, obtained by applying the unitary transformation $\mathcal{U}_{N,n}^{-1}$ defined by (47) to Ψ_N^{Lau} , is

$$\Psi_{n,N}^{\text{Lau}} = c_N \prod_{i < j} (b_i^\dagger - b_j^\dagger)^q \varphi_{n,0}^{\otimes N} = c_N \prod_{i < j} (b_i^\dagger - b_j^\dagger)^q \prod_{i=1}^N \left[\left(a_i^\dagger \right)^n \varphi_{0,0} \right] \quad (85)$$

with wave function (cf Proposition 3.1)

$$\Psi_{n,N}^{\text{Lau}}(\mathbf{r}_1, \dots, \mathbf{r}_N) = c_N \left[\frac{1}{(n!)^{N/2}} \prod_{i=1}^N (\bar{z}_i - \partial_{z_i})^n \prod_{i < j} (z_i - z_j)^q \right] e^{-(|z_1|^2 + \dots + |z_N|^2)/2}. \quad (86)$$

This is, in *electronic position variables*, the exact ground state of a Hamiltonian obtained by

- Projecting the Hamiltonian (58) onto $n\text{LL}^N$.
- Unitarily mapping the result down to an effective Hamiltonian on LLL^N using Theorem 5.1.
- Neglecting the one-body potential $V^{(n)}$ and truncating the Haldane pseudo-potential series (82) for the interaction potential $w^{(n)}$ at $m = q-1$.

Note that the pseudopotentials $w_m^{(n)}$ now depend on n because w is replaced by the effective interaction (63).

If the wave function (86) is transformed back to LLL^N using the representation of $\mathcal{U}_{N,n}^{-1}$ in terms of the integral kernel (76), we obtain again the function (83) but with the z_i replaced by the coherent state *guiding center variables* Z_i . Since the integral kernel is essentially concentrated in a disc of radius $\sim \sqrt{n+1} \ell_B$, one can expect that for large B and not too large n the particle densities of (83) and (86) are essentially the same in extended systems. This is indeed vindicated by the more detailed analysis mentioned below.

According to Laughlin’s plasma analogy (Laughlin, 1983) the density profile of (83) is for large N well approximated by a droplet of radius $(\ell N)^{1/2}$ and fixed density $(\pi q)^{-1}$,

$$\varrho_N^{\text{flat}}(\mathbf{r}) := \begin{cases} \frac{1}{\pi q} & \text{if } |z| \leq \sqrt{qN} \\ 0 & \text{otherwise.} \end{cases} \quad (87)$$

By a rigorous mean-field analysis it can be proved (Rougerie et al., 2014) that this approximation holds in the sense of averages over discs of radius N^α with $1/2 > \alpha > 1/4$. More generally, the k -particle densities are well approximated in this sense by the k -fold tensor power of the flat density if $N \rightarrow \infty$. The more refined analysis of classical Coulomb systems in Leblé and Serfaty (2018), Bauerschmidt et al. (2017) and Serfaty (2020) leads to an extension of this result down to mesoscopic scales N^α for all $\alpha > 0$.

¹Note that fermionic wave-functions do not see the even m terms of (81).

²For very strong interaction potentials of range much smaller than the magnetic length $\sim B^{-1/2}$, in particular if there is a hard core, an expansion of the interaction in terms of moments as in (81) is not adequate. This situation is analysed in Seiringer and Yngvason (2020) which generalizes the paper (Lewin and Seiringer, 2009). It is shown that in an appropriate scaling limit the pseudo-potential operators $|\varphi_m\rangle\langle\varphi_m|$ also emerge, but with renormalized pre-factors involving the scattering lengths of the interaction potentials in the different angular momentum channels, rather than expectation values as in (81).

Using the transformation formula (52) and the fact that the Laguerre polynomial $L_n(t)$ is close to unity for small values of the argument then allows to conclude the same result for fixed n and large N . The precise statement can be found as Theorem 8.1 in Rougerie and Yngvason (2020).

In order to adapt to an external potential V a natural modification of the Laughlin state is to insert *quasi-holes*, i.e., to consider states of the form

$$\Psi(z_1, \dots, z_N) = C'_N \Psi_N^{\text{Lau}}(z_1, \dots, z_N) \prod_{i=1}^N f(z_i) \quad (88)$$

where $f(z) = c \prod_{j=1}^M (z - a_j)$ with $a_j \in \mathbb{C}$. In Rougerie and Yngvason (2018) it is discussed how such states minimize the potential energy in an external potential among all states in the LLL which vanish like $(z_i - z_j)^q$ when two points come close. This result generalizes to higher Landau levels for large N by an analogous arguments as for pure Laughlin states, the intuition being again that in higher Landau levels position coordinates should be replaced by guiding center coordinates and the potential V by the effective potential $V^{(n)} = L_n(-\frac{1}{4}\Delta)V$.

Filling factor $\nu = 5/2$

A Quantum Hall state with a clear signature for filling factor $\nu = 5/2$ was first observed in Willett et al. (1987). It is thought to consist of *two* completely filled lowest Landau levels (i.e., with $n = 0$) but with opposite spin polarizations, combined with a spin polarized state with $n = 1$ and half filling. This state is unusual since the great majority of observed plateaus in the Quantum Hall conductance correspond to filling factors with an odd denominator as seemingly natural for fermions. Moreover, there is no sign of a plateau in the Hall resistance at $\nu = 1/2$ for $n = 0$ alone.

Since its discovery the $\nu = 5/2$ state has been extensively studied experimentally, see (Willett, 2013) for a comprehensive review. It is also very interesting theoretically because quasi-hole excitations of the principal candidates for describing this state may show *non-abelian* braid statistics. In brief, the reason is that the manifold of states with $2k$ quasiholes is 2^{k-1} degenerate and the braiding of two quasiholes defines a unitary map on the space spanned by this manifold. The unitaries corresponding to different braidings do not commute in general. An adequate discussion of these aspects would go well beyond the scope of the present chapter but a concise account with further references can be found in Tong (2016) as well as in Greiter (2011). A detailed discussion of non-abelian anyons and potential applications for quantum computation is given in Nayak et al. (2008). The recent review of Ma et al. (2022) discusses both theoretical and experimental aspects at filling factor $\nu = 5/2$. See also Greiner and Wilczek (2022) for a general review of fractional statistics.

The main candidates for the quantum Hall state at $\nu = 5/2$ are a *Moore-Read state* (Moore and Read, 1991) as well as its variant obtained by particle hole conjugation. A Moore-Read state in the LLL for an even particle number N and has the form

$$\Psi_{\text{MR}}(z_1, \dots, z_N) = \text{Pf} \left(\frac{1}{z_i - z_j} \right) \prod_{i < j}^N (z_i - z_j)^q \prod_{i=1}^N e^{-|z_i|^2/2} \quad (89)$$

with the Pfaffian

$$\text{Pf} \left(\frac{1}{z_i - z_j} \right) = \mathcal{A} \left\{ \frac{1}{z_1 - z_2} \dots \frac{1}{z_{N-1} - z_N} \right\} \quad (90)$$

where $\mathcal{A}$ stands for anti-symmetrization over all possible pairings of the coordinates. It has filling fraction $1/q$ and is antisymmetric for *even* values of q . It is also holomorphic because singular factors in the Pfaffian are compensated by the factors $(z_i - z_j)^q$. In contrast to the Laughlin wave function and its quasi-hole descendants the Moore-Read wave functions do not vanish when two particles come together, but may vanish when more particles become coincident. In particular for $q = 1$ it is a ground state of the formal 3-body Hamiltonian

$$H = \sum_{i < j < k} \delta(z_i - z_j) \delta(z_i - z_k). \quad (91)$$

The anti-Pfaffian state (Lee et al., 2007) is the particle-hole conjugate version of (89). The concept of particle hole conjugation is thoroughly discussed in Zirnbauer (2021), see also (Girvin, 1984). In the present case it means replacing the creation operators b_i^* by the annihilation operators b_i and applying the result to a fully occupied LLL state (the Fermi sea) rather than the gaussian ground state $\varphi_{0,0}^{\otimes N}$, cf. Eq. (3.1) in Zirnbauer (2021). The Fermi sea in the LLL is a Slater determinant and has a wave function as in (83) with $q = 1$. The explicit formula for the anti-Pfaffian state, given in Lee et al. (2007), is

$$\Psi_{\text{aPf}}(z_1, \dots, z_N) = \prod_{i < j}^N (z_i - z_j) \prod_{i=1}^N e^{-|z_i|^2/2} \times \int \prod_{\alpha=1}^N d^2 \eta_\alpha \prod_{i,\alpha} (z_i - \eta_\alpha) e^{-|\eta_\alpha|^2/2} \prod_{\beta < \gamma} (\eta_\beta - \eta_\gamma) \Psi_{\text{MR}}(\bar{\eta}_1, \dots, \bar{\eta}_N). \quad (92)$$

Yet another candidate for the quantum Hall state at $\nu = 5/2$ is a particle-hole symmetric state suggested in Son (2015).

All the states mentioned are specified in the lowest Landau level, where they are given by holomorphic wave functions. The general procedure of Sections “Unitary maps between Landau levels”, “Many body states and l-particle densities”, “Mapping Hamiltonians to the LLL”, “Remark”, “Another proof of Theorem 5.1”, “Coherent state representations” then takes care of lifting them up to any Landau level $n\text{LL}^N$. In the $\nu = 5/2$ case one takes $n = 1$ and assumes a fully spin polarized state. An important point is now that the effective interaction depends on the Landau level as described in Eq. (63). For instance, a Coulomb potential is more repulsive at short distances for $n = 1$ than for $n = 0$, (cf. Fig. 1 in Ciftja and Quintanilla, 2010). This may explain why, e.g. a Moore-Read state with $q = 2$ can have an energy gap in the $n = 1$ level and exhibit a FQHE plateau, while being a gapless Fermi liquid in the LLL.

The nature of the true ground state at $\nu = 5/2$ is, however, still a matter of considerable debate. The issues of spin polarization and the possibility of *Landau level mixing* play an important role here. In this chapter so far it has always been assumed that a single spin polarized Landau level, namely the highest partially filled one, is the arena for the phenomena under consideration while all lower levels are completely filled and can be regarded as inert. Landau level mixing means that the projection of the interaction Hamiltonian into a single Landau level is not adequate and processes where interactions induce transitions between different levels become relevant. Mathematically this means that it is not sufficient to consider states that are simply a tensor product of a state in a partially filled level with filled lower levels but one must consider states which are linear combinations of states with partial filling in more than one level.

Effective Hamiltonians to account for Landau level mixing at $\nu = 5/2$ were derived in Peterson and Nayak (2013), Simon and Rezayi (2013) and Sodemann and MacDonald (2013), and in Rezayi (2017) it was concluded that when mixing is allowed, an anti-Pfaffian state is favored. The effects of mixing may depend, however, on the size and shape of samples, and clear-cut answers for the thermodynamic limit are hard to come by. Moreover, the strength of the mixing depends on the material with e.g., ZnO showing stronger effects than GaAs. The paper (Luo et al., 2021) deals in particular with systems with strong mixing and the question of stability for incompressible ground states.

Conclusion

In this chapter it has been explained how quantum Hall states for many-body systems in arbitrary Landau levels can be mapped unitarily onto states in the lowest Landau level. The basis for this mapping is a splitting of the two-dimensional position variables into two sets of non-commutative variables associated respectively with the guiding centers and the cyclotron motion of the particles in the magnetic field. In a fixed Landau level the cyclotron variables play the role of bystanders while the state for the guiding center variables can be described by holomorphic wave functions independently of the Landau level. As a consequence, it is possible to treat particle densities and interactions in higher Landau levels in terms of suitably transformed densities and interactions in the lowest Landau level.

These insights are applied to Laughlin states in arbitrary Landau levels as well as to Pfaffian and anti-Pfaffian states that have been proposed for explaining pronounced quantum Hall plateaus at filling fraction $5/2$ and may exhibit non-abelian braid statistics of excitations. Their discussion in this chapter is quite brief, however, but detailed treatments of these matters are presented in other chapters of the Encyclopedia (Ma et al., 2022; Greiner and Wilczek, 2022).

Acknowledgments

Thanks are due to Nicolas Rougerie for collaboration on the review (Rougerie and Yngvason, 2020) which is the basis for the present chapter.

Abstract

Measurement of the Hall effect on a two-dimensional charge carrier system at low temperatures and high magnetic fields leads to the observation of well-defined Hall resistance values which remain constant against variation of the applied magnetic field or the charge carrier density—the quantum Hall effect (QHE). The quantized Hall resistance values depend only on the Planck constant h , the elementary charge e , and either an integer or a fractional valued number. The QHE has enabled in 2019 the redefinition of the International System of Units (SI), based now on five fundamental constants of nature. As described here, the robustness of the QHE is related to the evolution of an electrical compressible/incompressible landscape inside the naturally inhomogeneous charge carrier system with varying magnetic field/charge carrier density. The incompressibility has its origin in the formation of energy gaps, which arise—besides the formation of Landau levels—also by strong correlation effects between the charge carriers.

Key points

- The quantum Hall effect is observed, usually at high magnetic fields and low temperatures, on two-dimensional charge carrier systems in various materials, even with different band structures.
- The values of the quantized Hall resistance plateaus depend only on fundamental constants - the Planck constant h and elementary charge e , and an integer or fractional valued number ν .
- The quantum Hall resistance has been used as reference in metrology and has been a key to revise the International System of Units, now based on five fundamental constants of nature.
- If a certain relation between the charge carrier density and the magnetic flux density is fulfilled, an energy gap opens up, i.e., electrical incompressibility appears within the charge carrier system. As no states are present at the Fermi level, the local longitudinal conductivity becomes zero—the charge carrier system behaves locally as an insulator. However, local Hall conductivity exists and takes the value $\nu e^2/h$ where ν is an integer or a rational fraction, respectively.
- The formation of quantum Hall plateaus relies on inhomogeneities within the two-dimensional charge carrier density, either due to the natural depletion towards the edges or variations in the bulk due to disorder and imperfections.
- Due to these inhomogeneities, an electrically compressible/incompressible landscape is formed within the two-dimensional charge carrier system that evolves with varying either the magnetic field or the charge carrier density. Pathes of incompressibility might be present along the Hall bar over a larger range in magnetic field/charge carrier density.

[☆]Change History: September 2022. J Weis updated the chapter. Key points added, Figure 6 replaced. Figure 7 added. Sections on 'Role of Metal Contacts' and 'Breakdown' added. All Sections updated and extended. References added to the text.

- In the quantum Hall plateau regime, the bias voltage, applied to the Hall bar ends, is carried by the compressible regions along the Hall bar edges into the Hall bar and is then present as a Hall voltage over the Hall bar cross-section. In consequence, the local Hall voltage drop drives a dissipationless Hall current in the incompressible regions along the Hall bar.
- A well-defined quantized Hall resistance is measured if the Hall voltage in that cross-section drops only over incompressible regions of same integer or fractional ν .

Abbreviations

B	Magnetic flux density
c	Speed of light in vacuum
$D(\epsilon)$	Energy density of states
E	Electrical field
$-e$	Electron charge
e	Elementary charge

Introduction

The quantum Hall effect (QHE) and its relation to fundamental physical constants was discovered in 1980 by von Klitzing et al. (1980), and was honored by the Nobel prize in 1985 (von Klitzing, 1986). The Hall resistance R_H (Hall voltage divided by the applied current), measured on a two-dimensional charge carrier system at low temperatures (typically at liquid Helium temperature $T = 4.2$ K) and high magnetic fields (typically several Tesla) which is applied perpendicularly to the plane of the charge carrier system, shows well-defined constant values for wide magnetic field or charge carrier density variations. These plateau values are described by $|R_H| = h/(i e^2)$ where h is the Planck constant, e is the elementary charge and i an integer value with $i = \{1, 2, 3, \dots\}$. Nowadays this effect is denoted as integer quantum Hall effect (IQHE) since, beginning with the year 1982, plateaus have been found in the Hall resistance of two-dimensional electron systems of higher quality and at lower temperature which are described by $|R_H| = h/(f e^2)$ where f is a fractional number (Tsui et al., 1982; Laughlin, 1983). The fractions $f = \{1/3, 2/3\}$ are the most prominent ones. For the discovery of these unexpected new quantum states in 1982, manifesting themselves in the fractional quantum Hall effect (FQHE), Dan C. Tsui, Horst L. Störmer, and Robert B. Laughlin were honored by the Nobel prize in 1998.

The important implication of the integer quantum Hall effect was its application in metrology where the effect is used to represent a resistance standard. Due to the small standard uncertainty in reproducing the value of the quantized Hall resistance (few parts of 10^{-9}), its value was fixed in 1990 for resistance calibration purpose to 25812.807 Ohm and has been denoted as conventional von Klitzing constant R_{K-90} (Taylor and Witt, 1989). Recent developments try to establish the IQHE, measured under ac current modulation of few kilohertz (ac-QHE), even as primary standard reference for electrical impedances (Schurr et al., 2011).

It is generally accepted that the von Klitzing constant R_K agrees to h/e^2 . As in 1980 the speed of light c in vacuum and the permeability of vacuum μ_0 were fixed physical constants in the International System of Units (SI), R_K was directly related to the Sommerfeld fine-structure constant $\alpha = (\mu_0 c/2) (e^2/h) = (\mu_0 c/2) (R_K)^{-1}$, which is a measure for the strength of the interaction between electromagnetic fields and elementary particles. Therefore, it was also pointed out (von Klitzing et al., 1980) that the integer quantum Hall effect allows to determine the fine-structure constant α with high precision, simply based on magneto-resistance measurements on a solid-state device.

The most important impact in metrology however happened recently: The precision and the link of the QHE to the fundamental physical constant h —the fundamental constant of quantum mechanics—has enabled the redefinition of the International System of Units (SI) where the kilogram prototype (Davis, 2003) is replaced by a fixed value for the Planck constant. To ensure a smooth transition, a final value of h in the old SI base unit system was determined by Kibble balance experiments (Robinson and Schlamminger, 2016) where mechanical and electrical power are compared, taking use of the quantum Hall effect and the Josephson effect (Josephson, 1962). The revised SI unit system, effective since 20 May 2019, is now based on five exactly defined values for natural physical constants—the speed of light c , the elementary charge e , the Planck constant h , the Boltzmann constant and the Avogadro constant. By that, the von Klitzing constant R_K is fixed too—with an infinite number of digits in units of Ohm. The direct link to the Sommerfeld fine-structure constant α is lost as μ_0 became uncertain (von Klitzing, 2019).

Not only the application in metrology but mostly questions in fundamental physics have pushed the interest in the quantum Hall effect up to now. The fractional quantum Hall effect is a manifestation of strong correlation effects among the charge carriers interacting in the two-dimensional system that lead to the formation of new quantum states. With improving the quality and reaching lower temperatures for the charge carrier system, more and more quantum Hall states have been found, and even more might be discovered in the future. Quantum Hall systems are, therefore, used as model systems for studying the formation of strongly correlated many-particle states, developing theory for their description, and identifying, probably, their simpler description in terms of the formation of new quasi-particles, for instance, the so-called ‘composite fermions’ or ‘anyons’ (see further Contributions in this Encyclopedia).

Since 2007 the citations of the original QHE publication by von Klitzing et al. (1980) have risen significantly. The type of samples showing the QHE are nowadays considered as a special class of topological insulators, derived from the material’s band structure properties, widening also the material base for observing the QHE and related effects (see further Contributions in this Encyclopedia).

Hall effect

An electrical charge moving with constant velocity in a homogenous magnetic field feels the Lorentz force acting in a direction perpendicular to both the magnetic field orientation and the direction of motion. Driving a current through an electrical conductor (an experimental setup is shown in Fig. 1) leads to the Hall effect discovered by Hall (1879). As can be derived within the Drude model (Drude, 1900), the free charge carriers in the conductor accumulate due to the Lorentz force on one side and deplete on the opposite side leading to an electrical field (Hall field) in the conductor which in back-action compensates for the Lorentz force so that, under stationary conditions, the charge carriers drift straight through the sample. If only one type of charge carrier is present, the related Hall voltage V_H , that is, the difference in the electrochemical potentials between two contacts at opposite sample edges, where the connection line between these two contacts lies perpendicular to the current direction, is simply described by $V_H = V_y = R_H I_x$ with the Hall resistance R_H given by

$$R_H \equiv R_{xy} = B_z/(q n d)$$

Fig. 1 Setup for measuring the Hall resistance $R_{xy} = V_y/I_x$, the (four-terminal) longitudinal resistance $R_{xx} = V_x/I_x$, and the (two-terminal) longitudinal resistance $R'_{xx} = V_x'/I_x$.

for the orientation of the arrangement shown in Fig. 1. The Hall resistance is positive or negative depending on the type of charge carriers which are either electrons ($q = -e$) or missing electrons/holes at top of an else filled electronic band ($q = +e$). Its magnitude increases linearly with the homogeneously applied magnetic flux density B_z and the slope of the increase is given by the concentration n of these carriers and the thickness d of the conducting layer. That is why the Hall effect is used as an important diagnostic tool to determine essential properties of electrical conductors—free charge carrier concentration n and sign of q . Hall devices find various applications as magnetic field sensors.

Two-dimensional charge carrier system

The quantum Hall effect is observed in two-dimensional charge carrier systems, belonging to the class of so-called low-dimensional charge carrier systems. Simplified, the charge carriers in a bulk conductor can be considered as independent charged quasi-particles moving with an effective mass m^* freely in the three-dimensional space of the crystal. Such a charge carrier system is treated as the Sommerfeld fermion gas, that is, the wavefunctions of these quasi-particles are described by plane waves and their eigenenergies by $\varepsilon = \hbar^2 k^2 / (2 m^*)$, where $\mathbf{k}$ denotes the wavevector and $\hbar = h/2\pi$. The de Broglie wavelength $\lambda = 2\pi/|\mathbf{k}|$ of the charge carriers at their Fermi level in the bulky conductor (= Fermi wavelength λ_F) is given by $\lambda_F = h/\sqrt{(2 m^* \varepsilon_F)}$. Confining the charge carriers to spatial dimensions of the length of the Fermi wavelength λ_F , the charge carriers are restricted in their motion: Only certain eigenenergies are allowed in the confined direction, and the distance between these eigenenergies increases with narrowing the spatial width of the confinement, until only the lowest eigenenergy is still lying below the Fermi level. Two-dimensional charge systems allow motion only in a plane, one-dimensional charge systems—denoted as quantum wires—only along a line, and in a zero-dimensional system—denoted as quantum dots or ‘artificial atoms’—the charge carriers are confined in a cage allowing them overall only a discrete set of eigenenergies.

The Fermi wavelength $\lambda_F = h/\sqrt{(2 m^* \varepsilon_F)}$ of charge carriers in a bulky conductor is large in case of a low Fermi energy ε_F , achieved by a low charge carrier concentration n , and a low effective mass m^* . Therefore, semiconductors and especially the III–V compound semiconductor materials are preferred to define the low-dimensional charge carrier systems by confining conduction band electrons or valence band holes in one or more directions to few tens of nanometers or less. In this regard, the gallium arsenide (GaAs) stands out as in this case the band structure of the conduction band exhibits a single absolute minimum at the Γ point, and the dispersion relation is isotropic, described by a single effective mass $m^* = 0.067 m_0$ (where m_0 is the free electron mass).

The first two-dimensional charge carrier systems were realized in metal-oxide-semiconductor field effect transistors (MOSFETs) in the thin conducting channel at the insulator-semiconductor interface. Silicon-MOSFETs are used as electronic switches of which nowadays billions are integrated in modified design on a single microprocessor die. The quantum Hall effect was originally discovered on such a Si-MOSFET device (von Klitzing et al., 1980). Two-dimensional charge carrier systems of higher quality are obtained in layers or at interfaces of III–V compound semiconductor heterostructures which are fabricated by molecular beam epitaxy (MBE) or metal organic chemical vapor deposition (MOCVD). III–V semiconductor heterostructures find various applications as base material for low-noise and high-frequency transistors, as optoelectronic devices like light-emitting diodes and laser-diodes, or even integrated photonic circuits which belong nowadays to key elements in modern communication technology.

Highest quality two-dimensional electron systems are obtained in GaAs/Al_xGa_{1-x}As heterostructures based on modulation-doping (Dingle et al., 1978). The quality of conductors is usually characterized by the charge carrier mobility μ which relates, without an applied magnetic field, the drift velocity v_D of the free charge carriers to the applied electric field E by $v_D = \mu E$. As derived from the Drude model, the mobility is obtained from measuring the electrical conductivity σ via $\sigma = q \mu n$. The larger the absolute value of the mobility μ , the larger the distance a charge carrier can move without being scattered. Due to the spatial separation of dopants and free charge carriers in modulation-doped heterostructures, the scattering of the charge carriers on the ionized dopants is strongly reduced. At temperatures below 1 K, electron mobilities of more than $3 \times 10^3 \text{ m}^2/(\text{Vs}) = 3000 \text{ 1/T}$ have been reported in electron systems at such a heterojunction, allowing free mean paths of several 100 μm (Pfeiffer et al., 1989; Umansky et al., 2009). At room temperature such devices are used as high-electron mobility transistors (HEMT) in communication technology.

As shown in Fig. 2, for modulation doping, the donors are located in an Al_xGa_{1-x}As layer which has a conduction band bottom lying higher than that of bulk GaAs. The band offset is tunable by the ratio x by which gallium atoms are replaced by aluminum

Fig. 2 AlGaAs/GaAs heterostructure with a two-dimensional electron system (2DES) at the heterojunction in GaAs. Below: Sketch of the respective profile of the conduction band edge in z direction, and the two lowest subband energies $\varepsilon_{z,0}$ and $\varepsilon_{z,1}$ due to the triangular-shaped confining potential in z direction.

atoms on their crystal lattice sites. The electrons separate from their donors and accumulate in the GaAs at the heterojunction, because they are still attracted by the positively charged donor ions. Each electron feels a triangular shaped confining potential which restricts the electron motion to a free motion parallel to the heterojunction plane. If the electron density and the temperature are low enough, then only the lowest subband with energy $\varepsilon_{z,0}$ is occupied and the possible eigenenergies are described by

$$\varepsilon = |\hbar \mathbf{k}_{\parallel}|^2 / (2 m^*) + \varepsilon_{z,0},$$

where $\mathbf{k}_{\parallel}$ denotes the wavevector of the charge carrier in the plane of the 2D system. For the two-dimensional charge system with such a parabolic dispersion relation, the density of states $D_{2D}(\varepsilon)$ is constant,

$$D_{2D}(\varepsilon) = g_s m^* / 2\pi\hbar^2,$$

where the factor $g_s = 2$ takes into account the two possible spin orientations for each plane wave state characterized by the wavevector $\mathbf{k}_{\parallel}$.

In 2004 Andre Geim and Konstantin Novoselov (Nobel prize in 2010) introduced a fundamentally new type of two-dimensional charge carrier system—graphene, a single 2D crystal layer of carbon exfoliated from graphite as found in pencils (Novoselov et al., 2004). The type of charge carriers can be tuned electrostatically directly from electrons to holes by a gate electrode. Due to the linear dispersion relation in the band structure, the charge carriers behave as mass-less Dirac fermions. Meanwhile more 2D crystals have been realized, for instance from exfoliating transition metal dichalcogenides, and artificially stacking such layers leads to so-called van der Waals heterostructures (Ajayan et al., 2016).

Hall effect on two-dimensional charge carrier system—Quantum Hall effect

In Fig. 3, Hall resistance curves versus magnetic flux density are shown as they are measured on two-dimensional electron systems of different quality, embedded in (Al,Ga)As heterostructures as sketched in Fig. 1. At low magnetic fields, the Hall resistance is linearly increasing with the magnetic flux density B_z ,

$$|R_H| = |R_{xy}| = |V_y/I_x| = |B_z/(-e n_s)|, \quad (1)$$

and allows to determine the respective *sheet* charge carrier density n_s of the two-dimensional electron system. At higher magnetic field, the Hall effect on the two-dimensional charge system shows, in certain magnetic field ranges, values which are independent of the magnetic field. The values of these plateaus are perfectly described by

Fig. 3 Quantum Hall effect: Hall resistance R_{xy} and longitudinal resistance R_{xx} measured on a two-dimensional electron system embedded in (Al,Ga)As heterostructures of different quality as a function of the applied magnetic field. In certain magnetic field regions plateaus are observed in R_{xy} , and at the same time R_{xx} vanishes.

$$|R_H| = h/(v e^2) \quad (2)$$

where v is equal to an integer number $i = \{1, 2, 3, \dots\}$ or a certain fractional number f which seems to follow $f = p/q$ with $p = \{1, 2, 3, \dots\}$ and $q = \{3, 5, 7, \dots\}$, with exceptions like $f = 5/2$. The same plateaus are found by keeping the magnetic flux density B_z constant and varying the sheet electron concentration n_s . Therefore, varying the ratio n_s/B_z in certain ranges allows to observe Hall resistance plateaus described by Eq. (2).

Such Hall resistance values are expected due to the comparison between Eqs. (1) and (2) only for certain well-defined ratios $n_s/B_z = v e/h$. The meaning of this ratio can be expressed slightly differently: Taking a certain area A out of a homogeneous two-dimensional electron system enclosing the integer number $N = n_s A$ of electrons, the magnetic flux penetrating this area is given by $\Phi = A B_z$. The ratio between electron number N and magnetic flux Φ in units of the magnetic flux quantum $\Phi_0 = e/h$ is then

$$v = N/(\Phi/\Phi_0), \quad (3)$$

that is, for each electron, v^{-1} magnetic flux quanta are present.

Whenever in the Hall resistance a plateau is found, the (four-terminal) longitudinal resistance $R_{xx} = V_x/I_x$ vanishes, that is, $R_{xx} = 0$, – the occurrence of the Hall plateau is accompanied by a dissipation less current flowing along the sample. However, this does not mean that there is no dissipation at all: in the plateau regimes, the (two-terminal) resistance $R' = V_x'/I_x$ measured between the current biased contacts (see Fig. 1) is about the Hall resistance $|R_H|$, that is, the electrical power $|R_H| I_x^2$ is dissipated. The heat is created in two spot-like regions, one located close to each current biased contact. Along the sample away from the hot spot regions, dissipation is absent, indicated by the absence of a voltage drop along the sample. In the transition regimes between Hall plateaus, dissipation occurs along the whole sample, measurable by $R_{xx} \neq 0$.

The Hall plateau values for $i = 2$ and $i = 4$ are reproducible to the standard uncertainty of 10^{-9} , independent of the sheet charge carrier density, the sample geometry and further properties of the material in which the two-dimensional charge carrier system is embedded. That is why the quantum Hall resistance has been used since 1990 as a resistance standard. Si-MOSFET, but mostly (Al, Ga)As-HEMT devices have been applied for this purpose (Delahaye and Jeckelmann, 2003). In future, graphene-based quantum Hall devices might replace them due to moderate requirement on operation temperature and strength of magnetic field. Graphene shows signature of QHE even at room temperature at very high magnetic field (45 T) (Novoselov et al., 2007). Large areas of graphene are obtained on the surface of silicon carbide by thermal deposition, and seems to be the choice to realize a quantum resistance standard (Tzalenchuk et al., 2010). All these materials differ significantly in their band structure, but all show the QHE with high precision.

To trust in the plateau values obtained on a certain sample for metrological application, the flatness of the Hall plateau, the vanishing of the longitudinal resistance $R_{xx} = 0$, and the invariance of the Hall resistance with changing the temperature are checked (Delahaye and Jeckelmann, 2003). Increasing the quality of the samples, the Hall plateaus get smaller. In consequence, a certain amount of disorder is required to obtain well-defined Hall resistance plateaus and therefore accuracy in the quantized Hall resistance value. For metrological application, the sheet density n_s of the two-dimensional electron system in a GaAs/Al_xGa_{1-x}As heterostructure is typically in the range of $3\text{--}6 \times 10^{15} \text{ m}^{-2}$ with a mobility μ of $40\text{--}80 \text{ T}^{-1}$ and the measurements are done at the temperature $T = 1.5 \text{ K}$. For high-precision measurements, it is desirable to have the current level as high as possible. However, the current level is limited for the respective sample, since the quantum Hall effect breaks suddenly down with increasing the current beyond of a certain critical current level, denoted as electrically induced breakdown. The typical critical sheet current density I_x/w is in the order of $0.5\text{--}1.5 \text{ A m}^{-1}$. For metrology, typically Hall bar samples of several $100 \text{ }\mu\text{m}$ width are used. Also a significant increase of the working temperature degrades the Hall plateau, and the plateaus finally disappear.

Theoretical models for the quantum Hall effect

A complete microscopic theory still does not exist which allows to determine the quantum Hall plateau accuracy, flatness and width in real samples. However, the current distribution within the two-dimensional electron system for a robust quantum Hall plateau has been understood. It is commonly accepted that the integer quantum Hall effect can be described within a model of independent charge carriers, whereas for the fractional quantum Hall effect, many-particle correlations due to strong electron-electron interaction are of importance.

Integer quantum Hall effect

Starting at the late 1990s (McCormick et al., 1999; Weitz et al., 2000), spatially resolved measurements of the Hall potential profile with low-temperature scanning probe microscopes on two-dimensional electron systems embedded in GaAs-AlGaAs heterostructure devices have revealed the following microscopic picture of the integer quantum Hall effect (Weis and von Klitzing, 2011).

The single-particle energy spectrum—Landau levels

The magnetic field forces the electrons on cyclotron orbits. Quantum mechanically, the possible eigenenergies cluster in discrete Landau levels described by

$$\varepsilon = \varepsilon_{z,0} + (n + 1/2) \hbar \omega_c + s_z g^* \mu_B B \quad (4)$$

with the Landau level index $n = \{0, 1, 2, \dots\}$, and the spin quantum number $s_z = \{-1/2, 1/2\}$. The gaps between the Landau levels are either given by the cyclotron energy $\omega_c = \hbar eB/m^*$ minus the Zeeman energy $g^* \mu_B B$, or the Zeeman energy (μ_B denotes the Bohr magneton $\mu_B = e \hbar / (2 m_0)$ and g^* the effective Landé factor). The degeneracy $n_L = eB/h$ of each (spin-resolved) Landau level and the cyclotron energy ω_c increase with B . Therefore with increasing magnetic field, the electrons are redistributed to lower Landau levels leading to a sawtooth-like variation of the chemical potential $\mu_{ch}(n_s, B)$ for fixed sheet electron density n_s with increasing magnetic field (see Fig. 4). The ratio between the sheet electron density n_s and Landau level degeneracy n_L is denoted Landau level filling factor ν_L (or shortly filling factor),

$$\nu_L = n_s / n_L \quad (5)$$

Whenever the filling factor ν_L takes an integer value, the chemical potential lies energetically between two Landau levels, and in the homogenous electron system the respective fraction $\nu^{-1} = \{1, 1/2, 1/3, 1/4, \dots\}$ of a magnetic flux quantum is present for each electron, consistent with relation (3). For integer filling factors, the electron system behaves incompressible, that is, the compressibility κ becomes zero due to the jump in $\mu_{ch}(n_s, B)$ with increasing n_s ,

$$\kappa \propto (\partial \mu_{ch} / \partial n_s)^{-1} \rightarrow 0 \quad (6)$$

We will see, that the incompressibility, manifesting in relation (6), is a key to understand not only the IQHE, but also the FQHE.

Fig. 4 For an infinite homogeneous electron gas, the single-particle eigenenergy spectrum splits up into Landau levels with applying a strong magnetic field (in this sketch, the spin is neglected). The chemical potential varies in a sawtooth-like manner with increasing magnetic field.

Dissipationless current flow

For an infinite two-dimensional electron system with applied magnetic field in z direction and a homogeneous electric field in y direction, all Landau level states undergo a drift in x direction, so that the local sheet current density j_x in the x direction is given by

$$j_x = v_L e/h^2 E_y. \quad (7)$$

This Hall current flows without dissipation since this drift is a property of the eigenfunctions solving the respective Hamiltonian. To emphasize this, all occupied Landau levels contribute to the Hall conductivity $\sigma_H = v_L e/h^2$.

In fact, for any smoothly varying electrical field $E_y(y)$, the relation (7) remains locally valid (MacDonald et al., 1983). Integrating the sheet current density $j_x(y)$ over a certain width w in y direction, the integral current $I_x = \int_0^w j_x(y) dy$ is given by the voltage drop $V_y = \int_0^w E_y(y) dy$ over this width

$$I_x = v_L e/h^2 V_y, \quad (8)$$

and is therefore independent of the details of the Hall voltage drop along the y direction as long as v_L is constant where the Hall field E_y is nonzero within the width w . For integer values of the v_L , that is, whenever the electron system is incompressible, the Hall resistance values for Eq. (2) are obtained.

However, this does not explain Hall resistance plateaus. Here the theoretical models refer to disorder and inhomogeneity being present in real two-dimensional electron systems. Especially the edges of the sample and static potential fluctuations all over the sample lead to variations of the local filling factor within the two-dimensional electron system. Scanning probe experiments on (Al,Ga)As quantum Hall samples have shown (for a review see Weis, 2007) that the evolution of the electrical compressible/incompressible landscape due to these natural inhomogeneities inside the two-dimensional electron system allows for robust quantum Hall plateaus.

Compressible and incompressible regions within a two-dimensional electron system

A natural inhomogeneity, being present even in very clean samples, exists along the edges of the two-dimensional electron system. Within the depletion regions, the sheet electron density changes from zero to its bulk value over a typical distance of a few μm . Within this depletion region, the electrons have to rearrange themselves due to the electrostatic boundary conditions and due to the electrostatic interaction among them (electrostatic screening).

In thermodynamical equilibrium, the electron density profile can be calculated within a Thomas-Fermi approximation by (1) the constraint that the electrochemical potential μ_{elch} , that is, the sum of local chemical potential $\mu_{\text{ch}}(n_s(r))$ plus the electrostatic energy $-e\phi(r)$, is constant within the whole two-dimensional electron system, and (2) by the Poisson equation which relates the local electrostatic potential $\phi(r)$ to the local sheet electron density $n_s(r)$, taking into account the adequate boundary condition for $\phi(r)$ which are due to the respective sample. The problem can self-consistently be solved if (3) the chemical potential $\mu_{\text{ch}}(n_s, B)$ of the two-dimensional electron system is known as a function of the sheet electron density n_s . Here the situation without and with high magnetic field differs. This Thomas-Fermi approach is suitable for high magnetic fields where the magnetic length, $l = \sqrt{\hbar/eB} \approx 25 \text{ nm}/\sqrt{B[\text{T}]}$, becomes small (Lier and Gerhardt, 1994).

Without the applied magnetic field, the density of states is constant and therefore the chemical potential increases linearly with n_s , and the electron concentration rises smoothly at the edge towards the bulk (see Fig. 5). In contrast, with an applied high magnetic field, the density of states is discrete, the chemical potential increases in a step-like manner with increasing n_s , and therefore it is energetically favorable that the electron density profile shows regions of varying and of constant electron density. A strip-like structure is found along the edges (Chklovskii et al., 1992; Lier and Gerhardt, 1994), where the strips of constant electron density behave as a locally incompressible electron system whereas the regions of varying electron density are compressible. In compressible regions, occupied and unoccupied electronic states exist at the Fermi level, whereas in incompressible regions the Fermi level lies in an energy gap. They act insulating, that is, they suppress electron scattering between compressible regions. In the incompressible regions, the local Landau level filling factor $\nu_L(r)$ takes an integer value.

Fig. 5 Formation of compressible and incompressible strips within the depletion region along the edges of the two-dimensional electron system for a strong applied magnetic field.

In simplified terms, the position of an incompressible strip at a certain magnetic field can be identified within the electron density profile $n_s(r, B = 0)$ without magnetic field by searching for the local electron density $n_s(r)$ for which the incompressibility at that magnetic field is expected. The width of the incompressible strip at that position is larger, (1) the smaller is the gradient in $n_s(r, B = 0)$ at that position, and (2) the larger is the gap energy of the incompressibility. The electron density profile at the edges depends on the electron density in the bulk, and especially on the (electrostatic) boundary conditions at the edges, which are even affected by details of the device fabrication.

The gap energy of the incompressibility (cyclotron energy and Zeeman energy) rises with the magnetic field. Therefore, with increasing magnetic field, the strips shift away from the edges into the bulk as the same incompressibility is obtained for higher magnetic fields at larger electron density. They get broader as the electron density profile gets smoother towards the bulk. The strongest move is found for the respective innermost incompressible strip which merge from all depletion regions to an incompressible bulk at integer values of n_s/n_L (Chklovskii et al., 1992; Lier and Gerhardt, 1994). With further increase of the magnetic field, the next innermost incompressible strip with lower integer-valued filling factor takes the same evolution. This repeats down to filling factor one for the bulk.

The steeper the electron density profile, the smaller the width of the incompressible strip at the edges, that is, the outermost incompressible strips might become too small (below magnetic length) and therefore do not exist. It depends on the details of the sample. The energy gap due to the cyclotron motion is larger than that due to the Zeeman splitting in GaAs, which means that the incompressible strips with odd integer filling factor are narrower than those of even filling factor at the same position in the depletion region. Therefore, it is worth noting that the number of well-expressed compressible/incompressible strips at the respective edge is not strictly linked to the Landau level filling factor in the bulk. However, with increasing magnetic field, a widening innermost incompressible strip will appear in the depletion region before the bulk will become incompressible.

Increasing the magnetic field further, the bulk would switch immediately from the incompressible state to the compressible state. However, due to potential fluctuations within the bulk region of the real two-dimensional electron system, the local electron density $n_s(r)$ varies—a landscape of compressible and incompressible regions is formed also there which reshapes with varying the mean sheet electron density n_s or the magnetic field. Around integer values of n_s/n_L , the bulk is mainly incompressible with compressible droplets embedded. The range in magnetic field for which this regime exists depends on the sample quality—the cleaner the sample is, the smaller the magnetic field range. In case of large inhomogeneity, incompressible regions might appear already in the bulk while still an incompressible strip evolves from the edges.

Fig. 6 shows in sketches how the compressible/incompressible landscape within a two-dimensional electron system evolves over the range of a quantum Hall plateau. It turns out (Ahlsweide et al., 2002) that even in front of ohmic contacts the electron concentration is slightly reduced (presumably due to the work function difference between GaAs and the metal contacts), so that an incompressible strip might not only exist along the edges of the Hall sample but also in front of contacts. This evolution of the compressible/incompressible landscape inside the two-dimensional electron system governs how the biased current distributes inside the sample.

Current distribution in real samples

With these ingredients, the integer quantum Hall effect in (AlGa)As samples is roughly described by the following qualitative picture which repeats with rising magnetic field for the different quantum Hall plateaus.

With the application of an electrochemical potential difference between the source and drain contact, the electrochemical potential of source is carried by the compressible strips along one edge, the potential of drain by the compressible strips along the opposite edge into the sample (Fig. 6). A Hall voltage is present in the cross section over the Hall bar width. As a consequence, the Landau level bending in the respective cross section of the Hall bar width is affected. In Fig. 7 the Landau level bending with and without the Hall voltage is sketched for different situations along a quantum Hall plateau.

Fig. 6 Schematic evolution of the compressible/incompressible landscape within the two-dimensional electron system over a quantum Hall plateau. On low magnetic field side of a QH plateau, a well-expressed incompressible strip might exist along the edges of the quantum Hall sample, while at the higher magnetic field side the bulk is incompressible with embedded compressible droplets. Taken from Weis J, von Klitzing K (2011) Metrology and microscopic picture of the integer quantum Hall effect. *Philosophical Transactions of the Royal Society A* 369: 3954–3974.

Fig. 7 Bending of Landau levels in a Hall bar cross section in the bulk-dominated (a) and edge-dominated (b) quantum Hall regime without and with Hall voltage. Top and below: Respective current densities in the incompressible regions due to the local electric field, leading net to the distribution of biased current sketched at bottom. Adapted from Weis J, von Klitzing K (2011) Metrology and microscopic picture of the integer quantum Hall effect. *Philosophical Transactions of the Royal Society A* 369: 3954–3974.

In the situation sketched in Fig. 7a, the bulk is mainly incompressible with the local filling factor $\nu_L = i$. Due to the inhomogeneities within the electron density ('disorder'), compressible droplets are embedded. Already in thermal equilibrium, that is, equal electrochemical potential within the 2DES, the electrostatic potential varies owing to these inhomogeneities. Due to relation (7), local current densities encircle the compressible droplets, leading by integration within a cross section over the sample width to zero net current. This is also true for the current densities present owing to the electrostatic potential rises towards the edges:

the current densities on the left and right edges are oriented in opposite directions and compensate for each other. With a Hall voltage, that is, with an electrochemical potential difference between the edges, the compressible/incompressible landscape is affected: compressible droplet might rearrange, but the Hall voltage drops appear still as electrostatic potential drops only in the incompressible regions of $\nu_L = i$. Integrated over the whole sample width, a net current $I_x = (i e/h^2) V_y$ is obtained. Any variations in the compressible droplet landscape, for instance, by varying the applied magnetic field, affect the local current densities in the incompressible regions; however, they are not visible in the integral current. The relation between the integral current and the Hall voltage is stabilized. The current is driven in this cross section widely spread in the 2DES bulk as a Hall current without dissipation, carried by locally all occupied Landau level states, giving the well-defined Hall conductance. The amount of inhomogeneity of the bulk dominates the range in magnetic field stabilizing the situation, that is why this regime is denoted as bulk-dominated quantum Hall regime.

Towards the lower magnetic field side of the quantum Hall plateau, the compressible/incompressible landscape changes significantly. The bulk of the two-dimensional electron system becomes compressible, and incompressible regions are shifted into the depletion regions at the edges. Well-expressed incompressible strip might still exist along both edges of the Hall bar (Fig. 7b). In thermal equilibrium, current densities are present in the incompressible strips due to the rise in the electrostatic potential at the edges, however, as they are counterpropagating, they compensate for each other within the cross section. However, with a Hall voltage, the electrostatic potential drop inside the incompressible strip on one edge gets steeper, and on the other edge flatter. It means, compared to thermal equilibrium, the current densities are enhanced on one side and reduced on the other side, so that in net the biased non-equilibrium current flows equally distributed in the innermost incompressible strip along both edges of the Hall bar. As long as the Hall voltage drop happens only within these two incompressible strips of same filling factor, the relation $I_x = (i e/h^2) V_y$ is valid. This is the edge-dominated quantum Hall regime, usually extending the quantum Hall plateau to lower magnetic fields. Important is here, that the respective incompressible strips also exist in front of the metal contacts (Ahlsweide et al., 2002), otherwise this edge-dominated quantum Hall regime is suppressed as compressible edge and compressible bulk are locally equilibrated (electrically shortened).

With further lowering of the magnetic field, the incompressible strips move closer to the respective edge, get smaller, and finally are no longer able to withstand a Hall voltage drop. Electrons scatter from the compressible edge into the compressible bulk. Although the quantum Hall plateau regime breaks down, the Hall voltage drop might still strongly be confined to the edges; however, also in the bulk an increasing fraction of the drop is found. Before entering the regime of the next quantum Hall plateau at lower magnetic field, the drop is almost homogeneously distributed over the whole 2DES width (Ahlsweide et al., 2001).

Using the self-consistent evolution of the compressible/incompressible landscape in a narrow 2DES cross section, Siddiki and Gerhardt was able to calculate quantitatively a Hall resistance curve with quantum Hall plateaus for a two-dimension electron system which is constricted in the y direction and translation-invariant in the x direction (Siddiki and Gerhardt, 2004).

Role of metal contacts

Metal contacts to the 2DES are needed to bias the 2DES with a current and to probe the electrochemical potential at different positions along the Hall bar. From those, the Hall resistance and longitudinal resistance are determined.

In case of the bulk-dominated quantum Hall regime, the biased current distributes in the connected incompressible bulk. As the current flow is dissipationless, the compressible edge strips along the Hall bar form equipotential lines carrying the potential of the source or drain contact, respectively. It requires the longitudinal conductivity of the compressible strips to carry the respective electrochemical potential. To obtain the quantized Hall resistance value it is important that the Hall voltage drop happens only over incompressible regions of same integer-valued filling factor. If additional well-expressed incompressible strips of different filling factor exist in the depletion regions, the metal contacts have to suppress any Hall voltage drop over these incompressible strips. They have to ensure that the electrochemical potentials of all the compressible strips along the same edge are equilibrated by electrically shortening them. For (Al,Ga)As quantum Hall samples it is known that this depends on how the borderline between 2DES and alloyed metal is oriented relatively to the crystal orientation of the (AlGa)As heterostructure (Dahlem et al., 2010).

In case of the edge-dominated quantum Hall regime, well-expressed incompressible strips exist along the edges while the bulk is compressible. This regime is only measurable when the incompressible strips pass by in front of the metal contacts. It requires a partial depletion of the electron density, that is, an electron density profile to a lower $n_s > 0$ in front of the contacts which is indeed observed for (AlGa)As devices (Ahlsweide et al., 2002). Such a depletion can also be mimicked by electrostatic depletion due to a voltage-biased gate electrodes on top of the Hall bar finger towards the metal contact. To observe the expected well-defined Hall resistance value, the Hall voltage has to drop only over the innermost incompressible strip at both edges in a cross section. Again, here the metal contacts can ensure this.

Breakdown

At elevated temperatures, thermal excitations of electrons via the energy gap diminish the incompressibility. It leads to the thermally induced breakdown of the quantum Hall effect, that is, the longitudinal resistance rises and the quantum Hall resistance gets lost. The application of the QHE in metrology requires a high current level to ensure that current and voltages reach a level so that they are measurable with high accuracy. The level is limited by the electrically induced breakdown of the QHE.

In the edge-dominated quantum Hall regime, the width of the incompressible strips on both edges changes with rising Hall voltage (Gerhardt et al., 2013; Panos et al., 2014). This is due to the self-consistent rearrangement of electrons, reacting on the

additional voltage. With increasing Hall voltage, an asymmetry in the Hall potential drop—and therefore in the current distribution—arises continuously between the left and right edges of the Hall bar. This results in a dominant incompressible strip with enhanced electric field on one edge. A strong electric field bends the Landau levels, reducing also spatially their distance so that electron tunneling between the Landau levels might become possible (Eaves and Sheard, 1986). The insulating property of the incompressible strip is lost. On the other edge, that is, on the positive Hall voltage side, the possible Hall potential drop is limited by the quantization energy (Landau level or Zeeman energy gap). The width of the incompressible strip shrinks to zero. In consequence, electrons from the bulk may relax into the outer compressible edge by phonon and/or photon emission (Ikushima et al., 2004). As in the edge-dominated quantum Hall regime the 2DES bulk is compressible, its width of the bulk does not matter for the breakdown threshold, that is, the threshold in Hall voltage does not scale with Hall bar width (Haremski et al., 2020).

In the bulk-dominated quantum Hall regime, the Hall voltage drop is widely distributed over the bulk. Raising the Hall voltage leads to a rearrangement of the compressible droplets and affects therefore the incompressible paths along the Hall bar. The additional electrical fields within the incompressible regions scale with the Hall bar width for a given Hall voltage (Haremski et al., 2020). Therefore, wide Hall bars lead to high breakdown thresholds. The bulk-dominated quantum Hall regime is robust for metrological applications.

Localization

Since a certain amount of disorder is required to explain the occurrence of plateaus in the Hall resistance, the quantum Hall effect has been addressed from the beginning as a localization-delocalization phenomena of charge carriers in a random disorder potential (von Klitzing, 1986). The model of an incompressible and compressible landscape within the bulk region as depicted above is applicable in case of a smooth varying disorder potential, and takes electron-electron interaction self-consistently in an electrostatic manner into account. Other common models investigate the universality of the localization/delocalization phenomenon and the possibility of quantum phase transitions in such a quantum Hall system. The system is then discussed in terms of the density of states in energy where each Landau level is broadened in energy due to the static potential fluctuations. It turns out that states in the tails of the broadened Landau levels correspond to localized states, that is, they are not extended beyond a certain typical length under the respective conditions. Extended states exist only in the energetical center of broadened Landau levels. Localized states cannot contribute to Hall and longitudinal conductivity, that is, varying the Fermi level in the range of localized states, these states can be filled or emptied without affecting the transport properties—ingredients for the observation of plateaus in the Hall resistance.

Fractional quantum Hall effect

With increasing magnetic field, electrons finally end in the lowest Landau level. Here the electron-electron interaction becomes dominant leading to many-electron correlations, that is, their motions are not independent of each other. For certain fractional filling factors $\nu_L = \nu$, it has been found that the many-electron quantum state behaves incompressible and the respective charge excitations in the electron system are quasi-particles of fractional charge. In a later theoretical description, the electrons and flux quanta present in the system have been combined to new quasi-particles—so-called composite particles which have either fermionic or bosonic character depending whether the number of flux quanta attached to an electron is even or odd. This has simplified the picture of the fractional quantum Hall effect: Around fractional ν of even denominators, like $\nu = \{1/2, 3/2, 1/4, 3/4, 5/4, \dots\}$ composite fermions are formed which do not see any effective magnetic field at the respective filling factor ν . The larger the denominator, the more fragile are these composite fermions.

With varying magnetic field, these composite fermions survive and they feel now an effective magnetic field which enforces them to a cyclotron motion. Therefore, within the picture of composite fermions, the series of fractional quantum Hall states which lie symmetrically around $\nu = 1/2$ are interpreted as the integer quantum Hall effect of composite fermions consisting of an electron with two flux quanta attached (Stormer, 1999). This symmetry is also visible in the data for the FQHE in Fig. 3 around 12.6 T which corresponds to $\nu = 1/2$ in that sample: At $\nu = 1/2$, the composite fermion does not see any magnetic flux, i.e., $(\nu_{CF})^{-1} = 0$, whereas at $\nu \neq 1/2$, $(\nu_{CF})^{-1} = |\nu^{-1} - 2|$ flux quanta are present for the composite fermion. An integer filling factor $\nu_{CF} = \nu / |1 - 2\nu|$ is reached for the fractional filling factors $\nu = \{1/3, 2/5, 3/7, 4/9, 5/11, \dots\}$ and $\nu = \{1, 2/3, 3/5, 4/7, 5/9, \dots\}$. The fractional quantum Hall states $\nu = 2/3$ and $\nu = 2/5$ are therefore the integer quantum Hall states $i_{CF} = 2$ of this composite fermion. This picture gives a hierarchy to certain fractional quantum Hall states been observed.

Meanwhile, fractional states at higher Landau levels have been observed. The observed exotic fractional quantum Hall state $\nu = 5/2$ is interpreted as a pairing of composite fermions into a novel many-particle ground state. Although the experimental findings support the composite fermion picture, the theoretical foundation for this description is still under debate. A further discussion of correlated states at certain fractional filling factors is done by Papic and Balram within this Encyclopedia.

It is common to the fractional quantum Hall states that they are electrically incompressible due to strong electron-electron correlations. There exists an energy gap stabilizing the correlated electron state which appears for a certain fraction of the ratio between the numbers of electrons and magnetic flux quanta sharing a certain area. Scanning probe investigations have recently shown (Gauß, 2019) that the same evolution of Hall potential profiles and therefore current distribution is observed along

a quantum Hall plateau as for the IQHE described above. Edge- and bulk-dominated quantum Hall regimes are identified also for the FQHE.

IQHE and FQHE have in common the appearance of an incompressible state for certain electron densities at given magnetic field. As the property $(\partial\mu_{\text{ch}}/\partial n_s)^{-1} \rightarrow 0$ is valid in both cases, incompressible strips might be present in the depletion region along the edges. These incompressible strips with fractional filling factor evolve similarly to those with integer filling factor (Gauß, 2019): starting from the edges, with rising magnetic field, they shift towards the bulk, get wider and finally merge into an incompressible bulk. The strong electron-electron interaction in these incompressible states leads to correlations in the relative motion of the electrons, the common center-of-mass motion is still given by the group velocity of the single-particle states. The correlated state gets a drift velocity by the local Hall field, and as a well-defined number of occupied Landau level states contribute, the local current density is given by $j_x = v_L e/h^2 E_y$. Hall voltage drop only over incompressible region of same fractional valued filling factor leads to the quantized Hall resistance relation (2).

Conclusion

Self-consistent electrostatic screening, especially in the depletion regions at the edges, plays a very important role in the formation of quantum Hall plateaus in two-dimensional electron systems embedded in (Al,Ga)As Hall bar samples.

At the low magnetic field side of quantum Hall plateaus, well-expressed incompressible strips are present offering dissipationless paths for the biased current along both edges of the Hall bar. With increasing magnetic field, the innermost incompressible strips at the edges shift and widen until they merge into an incompressible bulk. Due to inhomogeneity of the electron density, compressible droplets are embedded which stabilize this incompressible/compressible landscape for a certain magnetic field range, until at higher magnetic fields the bulk becomes compressible, thus ending the quantum Hall regime. Such evolution has been found by scanning probe experiments both for integer and fractional quantum Hall plateaus.

The quantized Hall resistance is obtained whenever the Hall voltage drops within a Hall bar cross section exclusively over incompressible regions of same well-defined Landau level filling factor. That is why especially the Hall voltage drop over incompressible regions at the edges with lower filling factor have to be suppressed. Here the potential-probing metal contacts play a very important role to equilibrate the compressible strips along the respective edge. Samples for metrological application have to rely on inhomogeneity (=disorder) where the Hall potential drop and the current distribution are widely spread over the 2DES bulk. Here too, the contacts have to suppress any Hall voltage drop over incompressible strips of different filling factors at the edges.

Not only for the formation of a quantum Hall plateau but also for the electrically induced breakdown of the QHE, the electrostatic self-consistent evolution of the incompressible/incompressible landscape plays the key role. In case of the bulk-dominated quantum Hall regime, the threshold level scales with the Hall bar width, whereas in the edge-dominated quantum Hall regime, the threshold is indeed independent of the width.

The quantum Hall effect has been observed on two-dimensional charge carrier systems in materials with more complex band structures—such as graphene. Incompressibility is seen for different range of charge carrier densities and magnetic field than described by Eq. (5) (Novoselov et al., 2005; Zhang et al., 2005). Similar evolution of a compressible/incompressible landscape is expected and has indeed been seen (Panos, 2014) in forming quantum Hall plateaus.

Abstract

We review the network model for the integer quantum Hall effect. The model provides a simplified description of Anderson localization in this context. It represents non-interacting electrons moving in two dimensions under the combined influence of a strong magnetic field and a smooth disordered potential. In this setting, electron eigenstates form disorder-broadened Landau levels and their character varies with energy across the Landau level. States in both the low-energy and the high-energy tails of the Landau level are localized, with a spatial extent characterized by the localization length. At the center of the Landau level there is a transition between phases with different quantized values of the Hall conductance and the localization length is divergent. The network model captures universal features of this transition.

Key points

- The integer quantum Hall effect is a localization phenomenon.
- Transitions between states with different quantized values of Hall conductance are quantum phase transitions.
- The network model represents these transitions in a simple way.

Introduction

Soon after the discovery of the integer quantum Hall effect (IQHE) (Klitzing et al., 1980) it was realized that Anderson localization plays a central role in understanding what is observed (Aoki and Ando, 1981; Laughlin, 1981). More specifically, within a single-particle description, Anderson localization of electron eigenstates at some energies in a sample provides a way to understand the observation of plateaus in Hall conductance. This in turn implies that Anderson delocalization of eigenstates at other energies is responsible for transitions between different quantized values of Hall conductance as magnetic field strength or electron density are varied.

While quantization of Hall conductance was immediately acknowledged as a very significant discovery, appreciation of its broader importance has grown in dramatic ways since then. Three key developments are the TKNN topological interpretation of quantization (Thouless et al., 1982), the identification of the so-called 10-fold way for symmetry classes in Anderson localization (Altland and Zirnbauer, 1997), and the recognition of IQHE plateau phases as members of the broader class of topological insulators (Hasan and Kane, 2010).

Single-particle models for Anderson localization in the context of the IQHE can be formulated in a variety of ways (Huckestein, 1995). The essential ingredients that must be included are the effects of a strong magnetic field and of scattering by impurities. In addition, since computer simulation is the main tool for determining behavior, it is necessary to define a model in a way that facilitates numerical studies. There are three routes to the required discretization. One is to consider a tight-binding model with magnetic field included via the Peierls substitution, and impurities represented by random site energies. A second is to consider a strong-field limit in which impurity scattering can be restricted to states within a single Landau level. A third route starts from a scattering potential that is a smooth function of position. It leads, as we describe in this article, to the network model (sometimes referred to as the Chalker-Coddington model) (Chalker and Coddington, 1988). The model has the advantage of omitting details of the problem that turn out to be inessential, while retaining what is believed to be essential to capture the features of the quantum Hall plateau transition that are universal within a single-particle treatment.

The remainder of the article is organized as follows. In the section “Anderson localization and the integer quantum hall effect” we discuss the relation between Anderson localization and the IQHE. In the section “The network model” we formulate the network model, and summarize results of numerical studies of its properties. In the section “Generalizations of the network model” we introduce two generalizations of the network model. These represent plateau transitions in systems with symmetries that are different from those of the IQHE and that arise in certain superconductors. Finally, in the section “Conclusion” we summarize this discussion and point out some further related directions.

Anderson localization and the integer quantum hall effect

An outline of behavior observed in the integer quantum Hall effect is as follows. The experimental system consists of a two-dimensional electron gas in a strong perpendicular magnetic field and at low temperature. Electron eigenstates form a series of Landau levels and the most important control parameter is the Landau level filling factor ν . This indicates the number (not in general an integer) of Landau levels occupied by electrons and is given by the ratio of the electron density to the magnetic flux density. The behavior of the electron gas is probed by measurement of the diagonal and off-diagonal components of the conductivity tensor, σ_{xx} and σ_{xy} , with results of the form sketched in Fig. 1.

The Hall conductivity σ_{xy} as a function of ν exhibits a staircase, taking an accurately quantized value ne^2/h (with e the electron charge and h Planck's constant) over a range of filling factors around each integer filling n and rising rapidly from one quantized value to the next for ν mid-way between integer values. The behavior of the dissipative conductivity σ_{xx} is also distinctive: it is small within each Hall plateau and has peaks at the filling factors where the Hall conductance steps between quantized values.

This behavior can be understood on the basis of the picture shown in Fig. 2 for localization properties of single-particle eigenstates as a function of energy. Landau levels are broadened in energy by a disordered potential arising from randomly located donors in the sample, and the nature of eigenstates varies with energy across each Landau level. States in both the low-energy and the high-energy tails of each Landau level are localized with a size characterized by the localization length ξ , which is a function of energy. It is small in the tails of the Landau level but divergent at an energy near its center. In the simplest discussion, electron-electron scattering is represented by an inelastic scattering length ℓ_{in} which increases as temperature is reduced. States with $\xi < \ell_{in}$ are assumed not to contribute to transport, so that at low temperature only electrons in the small fraction of electrons near the center of each Landau level are mobile.

The form of the density of states is characterized by two energy scales: the width of a Landau level due to disorder, and the cyclotron energy $\hbar\omega_c$, which (omitting consideration of electron spin) is the separation between Landau levels. Standard conditions for the observation of the IQHE are, first, that the magnetic field should be strong enough for the cyclotron energy to exceed the Landau level width, and second, that the temperature should be low enough for the thermal energy to be less than the Landau level width.

Given the localization properties of electron eigenstates we have described, some of the main features in the dependence of the conductivity tensor on filling factor follow naturally. If ν is close to an integer value, the chemical potential lies within a band of localized states. In this case, small variations in ν alter the occupation only of localized states and not of current-carrying ones. The Hall conductivity is therefore independent of ν within this range: it exhibits a plateau. Moreover, under these conditions electron scattering can occur only between localized states within a thermal window around the chemical potential. Such scattering cannot cause dissipation and so σ_{xx} is small. By contrast, if ν is mid-way between two integers, the chemical potential lies near a Landau level

Fig. 1 Schematic illustration of the dependence of the Hall conductivity σ_{xy} and dissipative conductivity σ_{xx} on filling factor ν in an integer quantum Hall system.

Fig. 2 Properties of single-particle eigenstates in a model for the IQHE. The density of states $\rho(E)$ as a function of energy E forms a series of disorder-broadened Landau levels (two in this illustration). The nature of the eigenstates varies with energy across each Landau level as indicated: states in the low and high-energy tails are Anderson localized, but there is an energy near each Landau level centre where states are extended.

center and electrons in states close to the chemical potential are mobile. In this case, the Hall conductivity varies with ν , as is observed in the risers between Hall plateaus. In addition, scattering of electrons close to the chemical potential can give rise to dissipation, and so σ_{xx} displays a peak.

The discussion so far has been in terms of bulk properties of a system. It is also useful to take a complementary view by considering a system with a boundary, such as the Hall bars used experimentally. Modelling the boundary by a confining potential at the edge of the system, Landau levels rise in energy close to the sample boundary, as shown in Fig. 3. Then each Landau level that is filled in the bulk of the sample can be associated with an edge state at the boundary, where the level passes through the chemical potential (Halperin, 1982). These edge states are chiral, carrying current only in one direction along the boundary—behavior that is already apparent at a classical level from consideration of a skipping trajectory for a charged particle moving under the combined influence of a magnetic field and a confining potential.

At energies for which bulk states are localized, each edge state is isolated from its oppositely directed counterpart at the far side of the sample. Because electrons in isolated edge states cannot be backscattered by disorder, they evade Anderson localization. Instead, each edge state forms a perfectly transmitting channel. Applying this picture to a sample in which a current is flowing, the presence of a Hall voltage implies that there is a chemical potential difference between edge states on opposite edges of the sample. Moreover, the Landauer value for the conductance of a perfectly transmitting channel ensures that each occupied edge state contributes e^2/h to the Hall conductance (Büttiker, 1988). The absence of backscattering means that the chemical potential is constant along the length of each edge. In the geometry of a Hall bar, this means there is no voltage drop in the direction of current flow and hence no dissipation.

In summary, for a finite system with a boundary, the IQHE has an interpretation in terms of edge states. The value of the Hall conductance counts the number of edge states, and this number changes at quantum Hall plateau transitions. At energies for which bulk states are extended, edge states lose their identity because they mix with extended states in the bulk. In the absence of perfectly transmitting channels at the sample boundaries, the Hall conductance of a sample is unquantized and dissipation is not suppressed. Note that even when focusing on edge states in a discussion of the IQHE, the existence of localized bulk states in Landau levels tails is crucial. Specifically, for quantum Hall plateaus to have a finite width in ν , we require the chemical potential to remain between Landau level energies over a range of values of ν . This happens because small variations in ν change the occupation of localized states, so moving the chemical potential over a limited interval.

A framework for discussing transitions between quantum Hall plateau transitions is provided by scaling theory. Such a theory relies on an identification of the appropriate coupling constants that characterize behavior of a system across the transition. It aims to describe how these coupling constants evolve if a system is probed on an increasing length scale ℓ . It is justified if this evolution depends only the values of coupling constants themselves, and not on other properties of the system. For the plateau transition, these coupling constants are taken (on the basis of the field-theoretic formulation of the Anderson localization problem (Levine et al., 1982)) to be the two independent components of the conductivity tensor. A change in scale can be arranged experimentally by varying temperature (and hence ℓ_{in}) or in other ways, and in simulations by varying sample size.

The IQHE scaling flow (Kheml'nitskii, 1983) is shown in Fig. 4. For sufficiently small ℓ , the variation of the conductivity components with ν is smooth, as indicated by the dashed line in Fig. 4. Following the scaling flow, this smooth variation evolves with increasing ℓ into the sharp features of Fig. 1, since all trajectories lead to fixed points at large ℓ , and trajectories that are nearby initially may end at distinct fixed points. The fixed points are of two kinds, both labelled by integer n . Those at $(\sigma_{xx}, \sigma_{xy}) = (0, ne^2/h)$ represent quantum Hall plateau states and are stable in both directions. Those at $(\sigma_{xx}, \sigma_{xy}) = (\sigma_{xx}^*, [n + 1/2]e^2/h)$ represent transition points and are unstable to small deviations $\delta\sigma_{xy} = \sigma_{xy} - [n + 1/2]e^2/h$. The growth rate

$$\ell \frac{d\delta\sigma_{xy}}{d\ell} = \frac{1}{\bar{\nu}} \delta\sigma_{xy} \quad (1)$$

parameterized by $\bar{\nu}$ is a crucial property of the scaling flow. In particular, within a single-particle description of Anderson localization in quantum Hall systems, it follows from Eq. (1) that the localization length is a function of energy E , diverging at a critical energy E_c near the center of a Landau level as

$$\xi(E) \propto |E - E_c|^{-\bar{\nu}}. \quad (2)$$

Fig. 3 Edge states in the IQHE. Left: energy E of states in a disorder-broadened Landau level as a function of distance x from a sample boundary. For the indicated value of chemical potential μ , an extended edge state appears at the boundary. Right: classical skipping trajectory and directions of propagation of edge states at opposite boundaries of a sample displaying the IQHE.

Fig. 4 Scaling flow diagram for the IQHE. Each curve shows the trajectory followed by the coupling constants σ_{xx} and σ_{xy} with increasing ℓ . Different curves represent systems under different conditions (e.g. different $\bar{v}$) and the dashed line indicates how the coupling constants change as a function of v for small ℓ . See main text for further discussion.

Some of the objectives in modelling the IQHE are to test whether the scaling flow diagram shown in Fig. 4 is correct and to determine the value of $\bar{v}$. The unstable fixed points of interest lie at strong coupling (simulations suggest $\sigma^* \approx 0.5e^2/h$), presenting a challenge for analytical calculations, and so much of the information available is from numerical studies. The network model provides a starting point for these studies and potentially for analytical treatments. As we discuss in the section “The network model”, it also makes explicit the interplay between the idea of edge states and the formulation of the localization problem.

The network model

The network model gives a simplified representation of the Anderson localization problem for an IQHE system in which the potential due to disorder is smooth. More precisely, it is appropriate in the limit in which the characteristic length scale λ for fluctuations in the random potential energy representing impurities is much larger than the magnetic length ℓ_B , related to the magnetic flux density B by $\ell_B \equiv \sqrt{\hbar/eB}$. The ratio λ/ℓ_B is in fact the only dimensionless parameter that can be varied over a wide range without leaving the IQHE regime, since the other candidate, the ratio of the energy width of Landau levels to the cyclotron energy, is required to be small in order that Landau levels do not overlap in energy. We expect that critical behavior at the IQHE plateau transition is independent of the length ratio, so that the choice $\ell_B \ll \lambda$ is just one of convenience.

To study this localization problem we must find eigenstates of the Hamiltonian $H = H_0 + V(\mathbf{r})$, where H_0 is the usual kinetic energy for a charged particle moving in two dimensions with uniform magnetic flux density B , and $V(\mathbf{r})$ is a random function of position $\mathbf{r}$. If $V(\mathbf{r})$ is smooth, it is natural to start from a Taylor expansion of the potential, with the aim of finding local solutions to the Schrödinger equation that can subsequently be stitched together to form eigenstates in a large system. The network model is a representation of this matching process.

As a preliminary, it is useful to consider an equivalent classical problem in which a charged particle with cyclotron radius $r_c \ll \lambda$ moves in the same potential landscape. Its trajectory can be decomposed into a fast component, consisting of cyclotron orbits around a guiding center, and a slow component, consisting of drift of this guiding center along a contour of the potential. Correspondingly, the total energy is a sum of a kinetic contribution from the cyclotron motion and a potential contribution fixed by the drift contour. These two energies are separately conserved in a smooth potential, because in the smooth limit they are adiabatic invariants.

In the quantum-mechanical treatment, quantization of the fast component of motion yields a sequence of Landau levels, and states at different energies within a Landau level are associated with different contours of the potential. In this way, an eigenstate from the n th Landau level at energy $E = (n + 1/2)\hbar\omega_c + V$ has its probability density confined to a strip around the contour of the potential on which $V(\mathbf{r}) = V$, with the strip width set by the cyclotron radius $R_c = \sqrt{2n + 1}\ell_B$. This state carries probability current along the contour, mirroring the classical guiding center drift. Current conservation ensures that this probability current (integrated across the width of the strip) is independent of position along the length of any segment of the contour that is well separated from other segments of the same potential contour. On the other hand, near a saddlepoint in the potential where two segments come close together on the scale of R_c , quantum tunnelling is possible between them.

To formulate a model based on these ingredients, we divide the contour into individual segments that meet near saddlepoints, as illustrated in Fig. 5. These segments form links or edges of a graph that has saddlepoints as its nodes or vertices. The graph is a directed one, since each link has a unique direction for current flow, and it is generically fourfold coordinated, with two ingoing and two outgoing links at each node, since this is the description of a generic potential saddlepoint.

The features of the wavefunction that are relevant for localization are all contained in a set of complex scalar current amplitudes z_i , defined on the links i of the network. The value of $|z_i|^2$ gives the probability current carried by this link, and the phase of z_i is

chosen equal to that of the wavefunction at a convenient reference point on the corresponding segment of contour. Other details of the state (such as the dependence of the wavefunction on the transverse coordinate) are unimportant in our context.

Amplitudes on links that meet at a node are related by a scattering matrix S , which is constrained by current conservation to be unitary. Using the labelling given in Fig. 5, we can write

$$\begin{pmatrix} z_3 \\ z_4 \end{pmatrix} = \begin{pmatrix} e^{i\varphi_3} & \\ & e^{i\varphi_4} \end{pmatrix} \begin{pmatrix} \cos \alpha & \sin \alpha \\ -\sin \alpha & \cos \alpha \end{pmatrix} \begin{pmatrix} e^{i\varphi_1} & \\ & e^{i\varphi_2} \end{pmatrix} \begin{pmatrix} z_1 \\ z_2 \end{pmatrix}. \quad (3)$$

Here α , lying in the range $0 \leq \alpha \leq \pi/2$, is the key parameter, since (referring to Fig. 5) the probabilities for a particle incident on the node to turn either left or right are respectively $p = \sin^2 \alpha$ and $1 - p = \cos^2 \alpha$. Moreover, (again referring to Fig. 5) α is a monotonically increasing function of the energy V of the contour under consideration, since if V lies far below the energy of the saddlepoint, $p \rightarrow 0$, while if V lies far above this energy, $p \rightarrow 1$. At the saddlepoint, symmetry implies that $\alpha = \pi/4$ and $p = 1/2$.

The parameters $\varphi_1, \varphi_2, \varphi_3$ and φ_4 represent phases accumulated by electrons as they propagate between saddlepoints of the potential. Individually these phases are dependent on the choice of gauge, but the net phase accumulated around the boundary of any plaquette of the graph is gauge-invariant and equal to $2\pi(\Phi/\Phi_0)$, where Φ is the magnetic flux passing through this plaquette and Φ_0 is the flux quantum. Since $\Phi/\Phi_0 \sim (\lambda/\ell_B)^2$ is much larger than one in a smooth potential and varies with the area of the plaquette, it is natural to take the phases to be independent random variables uniformly distributed between zero and 2π . It remains to specify the the graph made up from these links and nodes. This is determined by the form of the potential energy $V(r)$ and an obvious choice would be a random geometry, following an underlying continuum percolation problem. It is more convenient, however, to consider a checkerboard potential that has maximum and minima regularly arranged on the plaquettes of a square lattice, with only a small additional random component. Then the graph likewise forms a square lattice, and we can take the value of the scattering parameter α to be the same at every node, so that randomness appears exclusively in the values of the phases φ_i . We expect from general notions of universality at a critical point that these simplifications will be unimportant as far as critical behavior of the IQHE plateau transition is concerned. With this choice, as illustrated in Fig. 6, directed links circulate in opposite senses around alternate plaquettes of the lattice: (say) clockwise around minima in the potential and anticlockwise around maxima.

We can now discuss how the network model gives a representation of quantum states for a system consisting of many links and nodes. In essence, we want to choose amplitudes z_i on each link i so that the scattering relations of Eq. (3) are satisfied at every node. There are differences in the logic required according to whether we are treating an eigenstate of a closed system or a stationary scattering state of an open system.

Fig. 5 Contours of a disordered potential $V(r)$. Local maxima and minima are labelled + and -. Arrows indicate direction of drift of cyclotron guiding centers in classical motion, and of current carried in quantum eigenstates. Points on four contour segments that meet at a saddlepoint are labelled 1, 2, 3 and 4 as in Eq. (3). The saddlepoint is marked with a dashed circle.

Fig. 6 Choice of square lattice graph for the network model, showing circulation in opposite senses around adjacent plaquettes of the lattice, which are respectively shaded and unshaded to indicate regions of low and high potential $V(r)$. Left: with closed boundary conditions. Right: with open boundary conditions.

For a closed system, the right-hand side of Eq. (3) at each node defines a 2×2 block of a unitary matrix $\mathcal{U}$. This matrix is of size $\mathcal{N} \times \mathcal{N}$, and acts on an $\mathcal{N}$ -component vector $\mathcal{Z}$ that has entries made up of the amplitudes z_i on all incoming links. The vector $\mathcal{U}\mathcal{Z}$ consists of the amplitudes on outgoing links that are compatible with these incoming amplitudes. Moreover, each link that is outgoing from a given node is also incoming at another node, and so the condition for a stationary state is that $\mathcal{U}\mathcal{Z} = \mathcal{Z}$. A closed finite system has a discrete spectrum, and at an energy not in the spectrum, there is no stationary state and so none of the eigenvalues of $\mathcal{U}$ are unity. Adjusting energy to locate eigenstates will change the positions of potential contours and hence the values of φ_i . We can represent this in a simple way by taking $\varphi_i \rightarrow \varphi_i + \phi$ with ϕ a function of energy. Then $\mathcal{U} \rightarrow e^{i\phi}\mathcal{U}$ and an eigenvector of $\mathcal{U}$ represents a stationary state at the energy for which the corresponding eigenvalue of $e^{i\phi}\mathcal{U}$ is unity. Note that although the scattering parameter α also varies with energy, it does so much more slowly by a factor $(\lambda/\ell_B)^2$ than the phases φ_i , and it is therefore appropriate to regard it simply as a parameter in $\mathcal{U}$.

In an open system, links can be divided into three groups: links that are internal; links that incoming from outside the system; and links that are outgoing. For example, in Fig. 6B there are two incoming and two outgoing links. The amplitudes on incoming links determine other all amplitudes, on both internal and outgoing links. These internal and outgoing amplitudes are the unique solution to the set of equations obtained by applying Eq. (3) at every node.

Edge states arise naturally within the network model when we consider the dependence of the system on the value of α . As discussed above, in the low energy tail of the Landau level $\alpha \rightarrow 0$, and in the high-energy tail $\alpha \rightarrow \pi/2$. In the first limit, the network model decomposes into a set of disconnected loops around minima in the potential. In the second limit there is a similar decomposition, but with loops around maxima in the potential and with the addition of an edge state at a sample boundary, as illustrated in Fig. 7. This evolution of geometry with α is precisely what is required to capture the edge state interpretation of the IQHE, introduced in the section “Anderson localization and the integer quantum hall effect”.

Our knowledge of behavior for intermediate values of α comes mainly from numerical calculations. These indicate that stationary states are indeed localized away from the critical point at the Landau level centre, where $\alpha = \alpha_c \equiv \pi/4$. The localization length ξ diverges as $\xi \sim |\alpha - \alpha_c|^{-\bar{\nu}}$ on approaching the critical point (Chalker and Coddington, 1988), while states at the critical point $\alpha = \alpha_c$ have a multifractal distribution of amplitudes z_i (Evers et al., 2008; Klesse and Metzler, 1995). Estimates of the value of the localization length exponent have improved in precision, from the initial result $\bar{\nu} = 2.5 \pm 0.5$ (Chalker and Coddington, 1988) to more recent studies yielding $\bar{\nu} = 2.62 \pm 0.06$ (Obuse et al., 2012; Slevin and Ohtsuki, 2009).

Generalizations of the network model

An obvious generalization of the network model described in the section “The network model” is to a version in which each link carries a number N of chiral channels with $N > 1$, so that the amplitudes z_k become N -component spinors. Then the random phase factors $e^{i\varphi_k}$ appearing in Eq. (3) should be replaced with random $N \times N$ unitary matrices V_k . Without any restrictions, this extended model exhibits transitions at N distinct values of α in the range $0 < \alpha < \pi/2$, each having the same critical behavior as in the model

Fig. 7 Limiting behavior in the low and high energy tails of a Landau level. Top: scattering at a node, for $\alpha = 0$ (low energy) and $\alpha = \pi/2$ (high energy). Bottom: network model as in Fig. 6A for $\alpha = 0$ (left) and $\alpha = \pi/2$ (right), showing appearance of edge state in second case.

with $N = 1$. At every transition, the number of edge states changes by one, as expected from the scaling flow diagram of Fig. 4 (Lee and Chalker, 1994).

Versions of the model with different critical behavior may arise if constraints are imposed on the choice of the unitary scattering matrices V_k on links. These constraints appear in treatments of quasiparticle scattering in gapless superconductors, starting from the Bogoliubov de Gennes equations, and fall within an overall classification scheme known as the 10-fold way (Altland and Zirnbauer, 1997). The specific possibilities of interest are termed class C and class D. In this physical situation, charge transport is short-circuited by the superfluid condensate and so quasiparticle properties must be probed via heat transport, or spin transport in systems for which spin is conserved.

Class C arises for superconductors in which time reversal symmetry is broken for orbital motion but spin rotation symmetry is preserved. To describe this situation, N is required to be even and V_k are $SP(N)$ matrices, with $N = 2$ and $Sp(2) \sim SU(2)$ as the simplest version (Kagalovsky et al., 1999). A notable feature in this case is that many disorder-averaged properties of this version of the quantum Hall plateau transition can be computed exactly via a mapping to models of classical percolation (Gruzberg et al., 1999).

Class D represents superconductors with neither time reversal nor spin-rotation symmetry. In this case the V_k are orthogonal matrices, reducing in the simplest version to signs ± 1 for $N = 1$. For models of this type, depending on details of the disorder, both localized and metallic phases are possible, as well as a distinct version of the quantum Hall plateau transition (Chalker et al., 2001).

Like the original model, these generalizations all capture transitions between localized phases that are topological in the sense that they are distinguished by the number of edge states they support.

Conclusion

In summary, we have described how the concept of Anderson localization is central to understanding the existence of the integer quantum Hall effect and the nature of transitions between quantum Hall plateau phases with different values of Hall conductance. For a sample with boundaries, the idea of edge states is also key in our description of the quantization of the Hall conductance. The network model uses the notation of edge states for internal regions of a sample as a way of formulating the localization problem in the language of scattering theory.

The discussion leading to the network model, as presented in the section “The network model”, can be supported by more detailed treatments of edge states (Halperin, 1982) and of scattering in a potential with a quadratic saddlepoint (Fertig and Halperin, 1987). In addition, for a smooth potential that has finite-range correlations in place of the checkerboard form discussed so far, the potential contours are cluster boundaries in a continuum percolation problem (Trugman, 1983). This raises a question of what the interplay is between such classical critical behavior and the IQHE plateau transition, and the answer depends on the regime. For such a potential at any fixed energy away from the Landau level center, behavior in the limit $\lambda/\ell_B \rightarrow \infty$ is governed by the classical description, because in this case the probability p of tunnelling takes the value either 0 or 1 at every node. On the other hand, for any large fixed value of λ/ℓ_B we expect crossover of critical behavior from classical, far from the transition, to quantum, close to the transition, with quantum critical behavior captured by the network model.

We have limited this article to consideration of the single-particle problem, with the consequences of electron-electron interactions summarized in terms of an inelastic scattering length, ℓ_{in} . For a more complete view of the quantum Hall plateau transition, one should regard it as a quantum critical point, with interactions and disorder treated on an equal footing at the outset: see for example (Sondhi et al., 1997).

While results for the critical behavior of network model have so far been derived mainly from numerical simulations, it is natural to hope that it can also be a starting point for an analytical treatment of the IQHE plateau transition. One avenue is provided by a mapping from the model to a form of quantum spin chain, in which disorder in a two-dimensional single-particle problem is traded for many-body interactions in a system in one space dimension (Bondesan et al., 2017). See (Zirnbauer, 2021) for a discussion of difficulties and recent progress.

Abstract

This article reviews the development of photonic analogues of quantum Hall effects, which have given rise to broad interest in topological phenomena in photonic systems over the past decade. We cover early investigations of geometric phases, analogies between electronic systems and the spectra of periodic photonic media including photonic crystals, efforts to generalize topological band theory to open, dissipative, and nonlinear wave systems, pursuit of useful device applications, and ongoing studies of photonic Hall effects in classical nonlinear optics and the quantum regime of strong photon-photon interactions.

Key points

- Review theoretical and experimental work on topological phases of light
- Emphasize similarities and differences compared to electronic quantum Hall effects
- Discuss possible device applications of photonic quantum Hall effects, including robust waveguides and lasers
- Outline new developments in the study of classical and quantum photonic topological systems

Introduction

The quantum Hall (QH) phase discovered in 1980, which arises in two-dimensional electron gases under a strong applied external out-of-plane magnetic field, represents the first example of a topological insulating phase of matter (von Klitzing et al., 2020). Such materials are distinguished by bulk band gaps in their band structures with gapless chiral edge states which propagate unidirectionally along the boundaries with a built-in topological immunity to backscattering from disorder.

The use of topological concepts to explain robust physical observables originated with the seminal works of Thouless et al. (Thouless et al., 1982; Kohmoto, 1985) connecting the experimentally observed quantized Hall conductance with a topological invariant, namely, the Chern number, defined in the momentum space. Studies of related topological insulating materials have attracted enormous interest from the mid 2000s until the present day.

*Corresponding author: e-mail address: daria.smirnova@anu.edu.au

Interestingly, topological phases are not limited to fermionic systems and can be translated to classical wave phenomena. Unusual manifestations inherent to topologically nontrivial states, including the ability of edge modes to overcome structural imperfections without back-reflection, drive general interest in topological and quantum Hall effects of classical waves, especially within photonics and optical communications (Ozawa et al., 2019; Smirnova et al., 2020).

Topological photonics has recently emerged as a novel approach to robust waveguiding and routing of light. It exploits engineered photonic structures (Lu et al., 2016) with properties analogous to electronic topological insulators (Hasan and Kane, 2010), which are insulating in their bulk but exhibit conducting states at their surfaces.

While discussions of photonic topological phases are usually framed as being inspired by and analogous to more widely-known electronic topological phases, closer inspection of the history of electronic and photonic topological effects reveals they are in fact closely intertwined. For example, the explanation of the quantum Hall effect in terms of the Chern number was quickly found to be related to geometric phases anticipated decades earlier in optics.

Here we will attempt to present a complete history of the study of photonic quantum Hall effects from its surprisingly early origins up to ongoing research. To keep this Chapter concise we will focus on two-dimensional photonic quantum Hall and spin-Hall effects, mentioning related topological phenomena (e.g. one-dimensional edge states, higher-order topological phases) only in passing and directing the interested reader to relevant in-depth reviews.

Overview

Historical background

The study of photonic quantum Hall effects can be loosely divided into three eras:

1. A pre-quantum Hall era of foundational theoretical and experimental works on optical beam and polarization shifts, now understood in terms of geometric phases.
2. A period of growing interest in analogies between condensed matter physics and photonics, culminating in the first observation of topological photonic edge states at microwave frequencies.
3. The topological photonics era, sparked by the crucial breakthrough that symmetry protection could circumvent the need for magneto-optic materials, opening up the exploration of topological phenomena to a wider variety of photonic systems.

Pre-quantum Hall era (1938–1980)

The Chern number underlying the quantum Hall effect is closely related to the parallel transport properties of quantum states, which form rays in Hilbert space. Already in 1938 Rytov found that classical rays of light undergo a polarization rotation under non-planar propagation (Rytov, 1938), shown in Fig. 1 for the case of light propagation in a twisted optical fiber. The polarization rotation is determined purely by the area enclosed by the trajectory, being an example of a geometric phase (Vladimirkii, 1941; Pancharatnam, 1956). Another foundational discovery was the Imbert-Fedorov shifts of reflected light beams (Fedorov, 1955; Imbert, 1972), which are now recognized as an example of spin Hall effects of light (Bliokh and Aiello, 2013).

Quantum Hall era (1980–2011)

Shortly after Thouless and collaborators explained the quantum Hall effect in terms of a topological invariant (Thouless et al., 1982), Simon (1983) showed how the invariant was related to the quantum geometric phase studied by Berry (Berry, 1984). While the first experimental observation of Berry's geometric phase as polarization rotation in a twisted optical fiber loop (Tomita and Chiao, 1986) argued it was a genuinely quantum mechanical effect that survives in the classical limit (Chiao and Wu, 1986), Haldane (1986) emphasized that this and earlier polarization rotation experiments by Ross (1984) could be understood purely classically using differential geometry. Nevertheless, these geometric phase experiments and theoretical proposals for photonic

crystals inspired by electronic band gaps (Yablonovitch, 1987; John, 1987) demonstrate the increasing cross-fertilization of ideas between quantum condensed matter physics and optics.

Haldane (1988) presented a condensed matter lattice model exhibiting a quantum Hall effect in the absence of a magnetic field, demonstrating how time reversal symmetry-breaking, not magnetic flux, underlies the quantum Hall effect. While the broad importance of this finding was not widely appreciated at the time (the article attracted only a few dozen citations over the next decade), Haldane's model formed the basis for the surge in interest in topological materials in the 2000s (Hasan and Kane, 2010).

The 1990s saw continued interest in geometric phase effects, including their influence on the semiclassical dynamics of wavepackets in periodic potentials studied by Niu – a former PhD student of Thouless – and his collaborators (Chang and Niu, 1995; Xiao et al., 2010). The semiclassical formalism showed how weak intrinsic Hall and spin Hall effects could be strongly enhanced in certain periodic potentials, inspiring further studies of spin Hall effects of electrons (Murakami et al., 2003; Kato et al., 2004) and photons (Onoda et al., 2004, 2006; Bliokh and Bliokh, 2004a, 2004b; Kavokin et al., 2005; Leyder et al., 2007).

Kane and Mele (2005a) showed that strong spin-orbit coupling may imitate the effect of a magnetic field in time-reversal invariant electronic systems, giving rise to a quantum spin Hall effect. Its simplest form constitutes essentially two time-reversed copies of the quantum Hall phase, where up and down spin electrons are decoupled and experience opposite effective magnetic fields. Remarkably, the quantum spin Hall effect is robust to coupling between the two spin sectors, forming a distinct topological phase of matter protected by time-reversal symmetry (Kane and Mele, 2005b).

Also in 2005, Haldane and Raghu proposed a photonic analogue of the quantum Hall effect in time reversal symmetry-breaking photonic crystals in a preprint that was only published in Physical Review Letters 3 years later (Haldane and Raghu, 2008). While potential applications as a basis for broadband unidirectional optical waveguiding were compelling, the weak strength of magnetic effects at optical frequencies suggested this proposal would be challenging to implement in practice. Wang et al. (2008) predicted that, even if an optical frequency realization might be impractical, the effect could be readily observed at microwave frequencies. Their seminal experiments using a magneto-optical photonic crystal shown in Fig. 2 demonstrated for the first time that robust quantum Hall-like edge states could be observed in photonic systems (Wang et al., 2009).

Topological photonics era (2011–present)

Present broad interest in topological bands and quantum Hall effects for photons was sparked by the discovery of several alternatives to weak magneto-optical effects:

1. Spin-selective excitations that effectively break the time-reversal symmetry of all-dielectric structures (Hafezi et al., 2011).
2. Suitably-designed temporal modulation of the coupling in optical resonator lattices that creates effective magnetic fields for light (Fang et al., 2012).
3. Waveguiding geometries with longitudinal refractive index modulations, where the propagation axis plays the role of “time” (Rechtsman et al., 2013).
4. Metamaterials that emulate the electronic spin-orbit coupling underlying quantum spin Hall phases (Khanikaev et al., 2013).

While these proposals each had their own limitations, (e.g. being limited to weakly-coupled cavity or waveguide lattices), more general and accessible designs soon followed, including all-dielectric topological photonic crystals (Wu and Hu, 2015; Ma and Shvets, 2016; Barik et al., 2016). There now exists a wide variety of approaches for generating quantum Hall-like edge states in photonic systems.

Theoretical and experimental approaches

To put photonic quantum Hall effects on a solid theoretical footing it is necessary to demonstrate a correspondence with the models of topological phases studied in condensed matter physics. On the other hand, the differences between Maxwell's equations for electromagnetism and the Schrödinger equation provide the opportunity to explore novel classes of topological phenomena inaccessible in electronic condensed matter systems.

Fig. 2 (A) Schematic of two-dimensional magneto-optic photonic crystal including a pair of antennas to measure the transmission of the photonic quantum Hall edge state past a strong scatterer. (B) Measured transmission spectrum from A to B (forward; blue) and from B to A (backward; red). Yellow shaded region denotes the topological band gap exhibiting strong unidirectional transmission. Modified from Wang Z, Chong Y, Joannopoulos JD, and Soljačić M (2009) Observation of unidirectional backscattering-immune topological electromagnetic states. *Nature* 461: 772–775.

Schrödinger formalism for electromagnetism

Consider the source-free Maxwell's equations for time t and space $\mathbf{r}$ -dependent electromagnetic fields $\mathbf{E}(\mathbf{r}, t)$, $\mathbf{D}(\mathbf{r}, t)$, $\mathbf{B}(\mathbf{r}, t)$, $\mathbf{H}(\mathbf{r}, t)$, in units with speed of light $c = 1$,

$$\nabla \times \mathbf{E} = -\partial_t \mathbf{B}, \quad \nabla \times \mathbf{H} = \partial_t \mathbf{D}, \quad \nabla \cdot \mathbf{D} = 0, \quad \nabla \cdot \mathbf{B} = 0, \quad (1)$$

$$\mathbf{D} = \varepsilon_0 \mathbf{E} + \mathbf{P}, \quad \mu_0 \mathbf{H} = \mathbf{B} - \mu_0 \mathbf{M}, \quad (2)$$

where ε_0 and μ_0 are the permittivity and permeability of free space, respectively, and $\mathbf{P}(\mathbf{r}, t)$ and $\mathbf{M}(\mathbf{r}, t)$ are the local polarization and magnetization densities of the material. A Schrödinger-like wave equation can be obtained by introducing the "wavefunction" $(\mathbf{E}, \mathbf{H})^T$ and assuming a linear constitutive relation between the fields, $(\mathbf{D}, \mathbf{B})^T = \hat{\mathbf{W}}(\mathbf{E}, \mathbf{H})^T$, corresponding to $\mathbf{P}$ and $\mathbf{M}$ being proportional to the local $\mathbf{E}$ and $\mathbf{B}$ fields,

$$i\partial_t \hat{\mathbf{W}} \begin{pmatrix} \mathbf{E} \\ \mathbf{H} \end{pmatrix} = \begin{pmatrix} 0 & i\nabla \times \\ -i\nabla \times & 0 \end{pmatrix} \begin{pmatrix} \mathbf{E} \\ \mathbf{H} \end{pmatrix}. \quad (3)$$

Assuming monochromatic fields with frequency ω , i.e. $(\mathbf{E}(\mathbf{r}, t), \mathbf{H}(\mathbf{r}, t))^T = e^{-i\omega t} \Psi$, and letting $\hat{\mathcal{H}} = (-\nabla \times) \otimes \hat{\sigma}_y$, we obtain the generalized electromagnetic eigenvalue problem

$$\omega \hat{\mathbf{W}} \Psi = \hat{\mathcal{H}} \Psi. \quad (4)$$

If the constitutive matrix $\hat{\mathbf{W}}$ is positive definite the generalized eigenvalue problem is Hermitian and supports a complete set of modes Ψ_n orthonormal with respect to the modified inner product,

$$\langle \Psi_m | \Psi_n \rangle = \int \Psi_m^* \hat{\mathbf{W}} \Psi_n d\mathbf{r} = \delta_{m,n}, \quad (5)$$

where $\delta_{m,n}$ is the Kronecker delta function. Therefore periodic electromagnetic media can be studied using standard tools from electronic condensed matter, including the decomposition of the spectrum into a band structure using Bloch's theorem.

There do however exist some peculiar differences between Schrödinger and electromagnetic waves. For example, the physical $\mathbf{E}$ and $\mathbf{H}$ fields are real-valued, demanding a particle-hole symmetry between positive and negative frequency modes of Eq. (4); this means the spectrum of $\hat{\mathcal{H}}$ is unbounded for both positive and negative frequencies, in contrast to the spectrum of the usual Schrödinger equation, which has a ground state. Moreover, the response of a material to an electromagnetic field is in general non-instantaneous; causality (Kramers-Kronig relations) requires the components of the constitutive matrix to be frequency-dependent and complex, i.e. $\hat{\mathbf{W}} = \hat{\mathbf{W}}(\mathbf{r}, \omega) = \hat{\mathbf{W}}^*(\mathbf{r}, -\omega)$. For further more rigorous discussion on the Schrödinger formalism for electromagnetism and implications for topological band theory, we recommend the article by [De Nittis and Lein \(2018\)](#).

Routes to topological bands

A spatially-periodic constitutive relation plays the role of a periodic potential in the electronic Schrödinger equation; appropriate choices of $\hat{\mathbf{W}}$ can therefore be used to create topological band gaps supporting photonic quantum Hall states. Different approaches are possible depending on the wavelength of interest λ and the scale of structural modifications a , summarized in [Fig. 3](#).

The most ubiquitous topological phases, in terms of characteristic topological invariants, are the Chern insulators characterized by the first Chern number. For a particular energy band, the Chern number is defined as an integral of the Berry curvature over the

Fig. 3 Summary of different approaches for realizing photonic quantum Hall and spin Hall effects, grouped according to the ratio of the operating wavelength λ to the modulation scale a . Note that generally a is less than structure periodicity d .

first Brillouin zone, $C_n = \frac{1}{2\pi} \int_{BZ} d^2k \Omega_n(k)$. A non-zero Chern number implies a discontinuity of Berry connection and emergence of the topological charge, which leads to the non-vanishing geometric phase term in an eigenvector. For finite systems, the bulk Chern number accounts for the number of unidirectional topologically protected edge modes (Hasan and Kane, 2010).

In two-dimensional Chern insulators the TR symmetry is necessarily broken, for example, by the magnetic field bias, and in finite Chern insulators the propagation direction of topological edge states is controlled by the sign of the total magnetic flux.

The original experiments of Wang et al. (2009) broke time-reversal symmetry by applying a magnetic field to a square-lattice photonic crystal of gyromagnetic ferrite rods confined vertically between two metallic plates to mimic the TM-polarized modes in infinitely long cylinders, shown in Fig. 2A. The resultant band structure hosts a gapless chiral edge state that propagates around defects with back scattering significantly suppressed and, by contrast, high transmittance within the band gap shaded yellow in Fig. 2B. Theoretically, the system is described by periodically-modulated scalar permittivity $\epsilon(\mathbf{r})$ and inverse permeability tensor

$$\hat{\mu}^{-1}(\mathbf{r}) = \begin{pmatrix} \tilde{\mu}^{-1} & i\eta & 0 \\ -i\eta & \tilde{\mu}^{-1} & 0 \\ 0 & 0 & \mu_0^{-1} \end{pmatrix}, \quad (6)$$

where the time reversal symmetry-breaking off-diagonal terms $\pm i\eta$ are induced by an external out-of-plane magnetic field. Eliminating the magnetic field $\mathbf{H}$ from Maxwell's equations Eq. (1) and introducing the "wavefunction" $\psi = E_z \sqrt{\tilde{\mu}}$, the eigenvalue problem reduces to (Wang et al., 2008)

$$-|\nabla + i\mathbf{A}(\mathbf{r})|^2 \psi + V(\mathbf{r})\psi = 0, \quad (7)$$

where

$$\mathbf{A} = \frac{\tilde{\mu}}{2} \hat{z} \times \nabla \eta, \quad V = \frac{1}{4} (|\nabla \ln \tilde{\mu}|^2 + |\tilde{\mu} \nabla \eta|^2) - \frac{1}{2} \nabla^2 \ln \tilde{\mu} - \tilde{\mu} \epsilon \omega^2. \quad (8)$$

Thus, the gyrotropic response produces an effective vector potential for light, which breaks time-reversal symmetry and can create topological band gaps with nonzero Chern number.

Unfortunately gyrotropic response is very weak at optical frequencies, severely limiting the size of any topological band gap. Therefore alternate approaches suitable for time reversal-symmetric dielectric materials are preferred. Synthetic gauge fields for light can also be introduced by periodic modulation of photonic crystal parameters in time or space. The effective magnetic field, associated with the complex phase accumulation, can thus force unidirectional propagation of photons without the use of magnetic materials at optical frequencies, in a way similar to electrons moving along skipping orbits along the edge in a two-dimensional magnetically-biased electron gas.

For example, light propagation in waveguide lattices formed by a weak modulation δn of the refractive index $n(\mathbf{r}) = \sqrt{\epsilon(\mathbf{r})} = n_0 + \delta n(\mathbf{r})$ is described by the paraxial wave equation (Rechtsman et al., 2013)

$$i\partial_z \psi(\mathbf{r}_\perp, z) = -\frac{1}{2k_0} \nabla_\perp^2 \psi - \frac{k_0 \delta n(\mathbf{r}_\perp, z)}{n_0} \psi(\mathbf{r}_\perp, z), \quad (9)$$

where $\mathbf{r}_\perp = (x, y)$ are the transverse coordinates, z is the propagation direction, and $k_0 = 2\pi n_0/\lambda$ is the wavelength of light in the medium. Since z plays the role of "time" in the paraxial equation, broken inversion symmetry $\delta n(\mathbf{r}_\perp, z) \neq \delta n(\mathbf{r}_\perp, -z)$ can be used to obtain nonzero Chern numbers for light propagating through the waveguide array.

The second most important class of topological phase is the quantum spin Hall or Z_2 topological insulator, which can be considered (loosely) as consisting of two copies of Chern topological insulators with gauge fields acting on opposite spins (Hasan and Kane, 2010). In fact, it is the time-reversal symmetry that ensures the topological stability of the edge states supported by quantum spin Hall topological insulators, with spin-orbital coupling, in the absence of spin-flipping processes. However, one should keep in mind that while time-reversal symmetry alone is sufficient to guarantee the presence of degenerate spin-1/2 states in condensed-matter physics, owing to Kramers' theorem for fermions, this is not the case for photons because they obey the bosonic quantum statistics. Therefore, additional deliberately-engineered symmetries related to pseudotime-reversal operators $\hat{C}_b, \hat{C}_b^2 = -1$, $\hat{C}_b \hat{\mathcal{H}} \hat{C}_b^{-1} = \hat{\mathcal{H}}$ are required in photonics to mimic the fermionic property of electrons $\hat{T}_f^2 = -1$, with time-reversal operator $\hat{T}_f = i\hat{\sigma}_y \hat{K}$, and achieve time-reversal-invariant topological order (Ozawa et al., 2019). They include internal symmetry of the electromagnetic field inside a photonic structure or crystalline symmetries of a photonic lattice. Such symmetries can produce modal degeneracies in a band structure, generating doublet states to emulate the pseudospin degree of freedom, thus enabling photonic analogues of the quantum spin-Hall effect (Khanikaev and Shvets, 2017).

For example, metamaterials formed through subwavelength modifications to the material properties can be used to engineer constitutive relations not found in natural materials, including negative refractive indices and strong coupling between electric and magnetic field components. Khanikaev et al. (2013) exploited this tunability to engineer two-dimensional metamaterials with bianisotropic coupling between transverse electric (TE; H_z) and transverse magnetic (TM; E_z) field components,

$$\left(k_0^2 \mu_{zz} + \nabla_\perp \frac{1}{\epsilon_\perp} \nabla_\perp \right) H_z = \left[\nabla_\perp \left(\frac{-i\chi_{xy}}{\epsilon_\perp \mu_\perp} \right) \times \nabla_\perp E_z \right]_z, \quad (10)$$

$$\left(k_0^2 \epsilon_{zz} + \nabla_{\perp} \frac{1}{\mu_{\perp}} \nabla_{\perp}\right) E_z = \left[\nabla_{\perp} \left(\frac{-i\chi_{xy}}{\epsilon_{\perp} \mu_{\perp}}\right) \times \nabla_{\perp} H_z\right]_z. \quad (11)$$

By engineering the metamaterial parameters such that $\mu_{zz} = \epsilon_{zz}$ and $\mu_{\perp} = \epsilon_{\perp}$, the electric and magnetic field components become degenerate. Consequently, bianisotropic coupling $\chi_{xy} \neq 0$ then gives rise to new eigenmodes $\psi_{\pm} = E_z \pm H_z$ emulating the quantum spin Hall phase.

Key issues

Are photonic quantum Hall effects genuinely robust?

The exact correspondence between electronic and photonic quantum Hall effects only holds under certain idealized conditions, including the absence of losses and optical nonlinearities. Remarkably, studies of the robustness of topological photonic edge states under non-ideal conditions have lead to the discovery of new kinds of topological phenomena in both photonic and condensed matter systems.

Losses and non-Hermitian topological phases

Early works on photonic topological edge states already recognized that unavoidable absorption, radiation, and scattering losses in photonic systems would place practical limits on their robustness and lifetime (Wang et al., 2009).

Material absorption is a fundamental property of optical media that cannot be eliminated via collective (band structure) effects. In fact, topological band structures typically emerge from confinement or multiple scattering, slowing down light propagation and enhancing absorption compared to homogeneous systems (Baba, 2008).

Radiation and scattering losses occur because there is no topological robustness of two-dimensional photonic quantum Hall effects against out-of-plane propagation. Modes of quasi-two-dimensional slabs with momenta above the light line will couple into the continuum of free space, resulting in radiative decay (Gorlach et al., 2018). Nominally-bound modes below the light line can still couple to radiation modes and acquire a finite lifetime in the presence of fabrication defect-induced scattering, such as roughness at boundaries between different materials comprising the slab (Sauer et al., 2020). To avoid out-of-plane scattering it is necessary to embed the planar photonic crystal in a three-dimensional photonic crystal supporting a complete omnidirectional band-gap at the frequency of interest.

Generally losses are manageable at microwave frequencies, where metals are good conductors and can provide perfect in-plane confinement and low-loss dielectric materials exist. At higher frequencies (terahertz and above) losses typically increase and feasible refractive index contrasts are weaker, making in-plane confinement harder. One way losses can be managed is by introducing optical gain (amplification), but this often brings about separate issues including amplification of noise and instabilities.

Regardless of their microscopic origin, the influence of loss and gain can be modelled by non-Hermitian effective Hamiltonians. Initial theoretical studies of the one-dimensional Su-Schrieffer-Heeger model suggested topologically-protected bulk (Rudner and Levitov, 2009) and edge (Schomerus, 2013) phenomena could still persist in non-Hermitian systems, subsequently observed using optical waveguide arrays (Zeuner et al., 2015) and microwave resonator chains (Poli et al., 2015). Later studies have generalized these ideas to two-dimensional topological phases (Ozawa and Carusotto, 2014) and observed non-Hermitian topological phenomena in a variety of systems including photonic crystal slabs (Zhen et al., 2015; Zhou et al., 2018) and microring resonator lattices (Zhao et al., 2019). Bergholtz et al. (2021) provide a more comprehensive review of non-Hermitian topological band theory.

Symmetry-breaking perturbations

Even if losses can be perfectly eliminated or compensated, disorder and imperfections can still spoil the robustness of most photonic quantum Hall effects; only systems that break time-reversal symmetry can be genuinely robust to all kinds of (Hermitian) perturbations.

The time reversal-symmetric systems supporting spin Hall effects most widely used in photonics do not share the robustness of their electronic counterparts; the robustness of the electronic quantum spin Hall effect is due to backscattering suppression protected by the $\hat{T}_f^2 = -1$ fermionic time-reversal symmetry. As noted in Section “Theoretical and Experimental Approaches,” the photonic time-reversal symmetry ordinarily obeys $\hat{T}_b^2 = +1$; fermionic $\hat{C}_b^2 = -1$ requires introduction of auxiliary spin-like degrees of freedom, such as valley or polarization (Khanikaev et al., 2013). Since this spin is not intrinsic but emerges due to structural properties, certain structural imperfections and lattice terminations can spoil the protection and induce backscattering (Saba et al., 2020).

For example, the valley Hall photonic crystals only support robust edge states in the absence of coupling between their two valleys. Short-scale structural deformations can induce inter-valley scattering that localizes the edge states. Similarly, topological crystalline phases such as the shrunken-expanded hexagonal photonic crystal design of Wu and Hu (2015) are protected by crystalline rotational symmetries. Typically, the symmetry is broken locally at domain walls or edges, inducing small gaps in the spectra of the interface states (Xu et al., 2016).

Therefore topological robustness of symmetry-protected photonic quantum Hall effects only holds to the extent that the underlying symmetries can be preserved. This poses a challenge because fabrication disorders will typically not preserve any spatial symmetries.

Optical nonlinearities

What is remarkable about electronic quantum Hall effects is that, even though the basic physics can be captured by simple single particle band structures, they are robust to electron-electron interactions and other many-body effects, giving rise to robust quantized transport. It is thus interesting to ask whether similar robustness can hold for classical waves in the presence of nonlinear interactions. This is another frontier of studies of photonic quantum Hall effects, reviewed by Smirnova et al. (2020).

Theoretical works have predicted that nonlinearities can lead to self-focusing (Leykam and Chong, 2016), instabilities (Lumer et al., 2016), and nonlinear localization (Lumer et al., 2013), potentially destroying robust transport. Nonlinearities also induce coupling between different linear modes of the system, potentially channeling energy between robust edge states into non-robust bulk modes (Xia et al., 2020). On the other hand, nonlinear pumps can be used to break time-reversal symmetry (Bardyn et al., 2016) and induce robust transport of weak probe beams (Peano et al., 2016).

Experimental studies on the effect of nonlinearities on photonic quantum Hall edge phases have observed a variety of effects, including frequency conversion (Mittal et al., 2018; Smirnova et al., 2019), bulk soliton generation (Mukherjee and Rechtsman, 2020), nonlinearity-induced edge states (Maczewsky et al., 2020; Mukherjee and Rechtsman, 2021), and nonlinearity-induced higher-order topological phases (Kirsch et al., 2021).

Since the dynamics of nonlinear systems cannot be completely characterized in terms of a unique spectrum or band structure, and are sensitive to the initial state and input intensity, rigorously demonstrating topological robustness in nonlinear wave systems is quite challenging. One notable example of where nonlinear robustness has been predicted and observed is in quantized Thouless pumping induced by periodic modulation of system parameters (Jürgensen et al., 2021), as shown in Fig. 4. Following a complete modulation cycle the soliton solutions must be identical up to translation invariance, thus solitons must be pumped a quantized integer number of unit cells. This number can change as the input power is varied due to nonlinear bifurcations.

Potential device applications

Electronic quantum Hall effects are useful as the electrical resistance standard, thanks to their unexpectedly extreme robustness (von Klitzing et al., 2020). On the other hand, photonic quantum Hall edge states have required clever and careful designs to observe, with claims of robustness typically based on the introduction of specific controlled perturbations. Will photonic quantum Hall effects also see useful applications? A few directions are currently being pursued.

Topological waveguides and cavities

Robust broadband non-reciprocal optical waveguiding was the first key application proposed for photonic quantum Hall effects (Haldane and Raghu, 2008), however, practical implementations competitive with the best conventional waveguide designs remain out of reach, in part due to the limitations to topological robustness leading to enhanced losses and nonzero backscattering (Sauer et al., 2020) discussed in Section “Are photonic quantum Hall effects genuinely robust?”

Fig. 4 (A) One-dimensional periodically-modulated waveguide array implementing a Thouless pump. (B) Instantaneous nonlinear spectra during one modulation cycle. Low power solitons are pumped one unit cell per modulation cycle, whereas high power solitons remain pinned to the initial unit cell. (C) Experimental observation of quantized Thouless pumping of solitons. Low power output profile is displaced one unit cell with respect to the input waveguide (white circles), while output becomes pinned to input unit cell at high powers. Modified from Jürgensen M, Mukherjee S, and Rechtsman MC (2021) Quantized nonlinear Thouless pumping. *Nature* 596(7870): 63–67.

Fig. 5 Examples of topological waveguides and cavities. (A) A domain wall between inequivalent topological phases (denoted by $m < 0$ and $m > 0$) results in a localized mid-gap mode in 1D systems and a unidirectional edge state in 2D systems. (B) Generation of robust 2D localized mode using a vortex-like modulation of the topological gap parameter $\mathbf{m}$. (C) Topological ring resonator coupled to a waveguide using topological domain walls in a 2D system.

Topological phases have also been considered as a way to create robust localized modes and resonators for light, with some examples illustrated in Fig. 5. The simplest approach is based on mid-gap localized modes appearing in one-dimensional photonic crystals (Malkova et al., 2009). Subsequently, topological resonators based on rings of valley Hall edge states (Ma et al., 2019b), topological corner modes (Mittal et al., 2019), and topological vortex defect modes (Gao et al., 2020) have been investigated. Kim et al. (2020) provide a more in-depth review.

One issue of vital importance to the design of waveguides and cavities is the device footprint. For example, in the case of two-dimensional quantum Hall edge states, robustness against backscattering is provided by the two-dimensional bulk. If one attempts to minimize the device footprint by reducing the size of the bulk, coupling between opposite edges will spoil the topological protection. Thus, topological waveguides and resonators tend to have a larger physical size (constrained by the size of the topological band gap) compared to conventional waveguides and resonators. This limitation needs to be taken into account when comparing the performance of topological and non-topological designs.

A more comprehensive overview on the design of topological photonic crystal waveguides and cavities is given by Iwamoto et al. (2021).

Topological lasers

Lasers are arguably one of the most important inventions of the 20th century and are now ubiquitous in a range of communication, sensing, and fabrication technologies. Naturally there has been tremendous interest in studying whether photonic quantum Hall edge states or other topological phases can serve as the basis for new and improved laser designs with better performance.

The first experiments combining optical gain media with topological photonic systems considered mid-gap modes of one-dimensional lattices (St-Jean et al., 2017; Zhao et al., 2018; Pardo et al., 2018). Bahari et al. (2017) observed lasing of quantum Hall edge states using the magneto-optic photonic crystal shown in Fig. 6, exploiting the fact that light emission from a continuous wave laser is intrinsically narrowband, which makes the weak magneto-optic response at optical frequencies sufficient to resolve localized edge states.

The first observation of lasing of quantum spin Hall states by Bandres et al. (2018) employed ring resonator lattices. Lasing in the spin Hall phase was observed to spontaneously break time-reversal symmetry, resulting in chiral light emission. Since lasing modes based on two-dimensional edge states appear to be insensitive to the shape of the boundary, they offer a potential route towards designing large cavities robust to fabrication disorders.

Since these seminal experiments numerous follow-up theoretical and experimental studies have been performed, considering different cavity designs and dimensions and various pumping schemes, reviewed by Ota et al. (2020). Efforts now focus on two complementary directions: (1) How to maximize the modal volume while preserving stable single mode lasing, and (2) how to reduce the mode volume and increase the quality factor to design highly efficient, low power lasers.

Fig. 6 First two-dimensional topological laser. (A) Band structure of the InGaAsP-YIG photonic crystal. Under an applied magnetic field, the YIG gyrotropic response breaks time-reversal symmetry, opening a small topological band gap with nonzero Chern number (green shaded region in inset). (B) Topological cavity formed by irregular boundary between inner topological photonic crystal and outer trivial photonic crystal. (C) Image of the device under high power optical pumping, revealing emission from the topological edge mode. Modified from Bahari B, Ndao A, Vallini F, Amili AE, Fainman Y, and Kanté B (2017) Nonreciprocal lasing in topological cavities of arbitrary geometries. *Science* 358(6363): 636–640.

The best route towards maximizing the modal volume remains under debate. Competing approaches include 2D quantum Hall-like edge states (Bandres et al., 2018), valley-Hall modes at domain walls (Zeng et al., 2020), bulk modes (Shao et al., 2020), vortex defect modes (Gao et al., 2020; Yang et al., 2022), and Dirac point modes of gapless band structures (Contractor et al., 2022). On the other hand, one obstacle against small modal volumes is that topological effects are a collective lattice property; protection is provided by having a sufficiently large bulk. It seems difficult to reduce the modal volumes below that achievable using a single isolated resonator or defect cavity; the main benefit of the topology may be in achieving a robustness to disorder at the expense of a larger modal volume.

On the theory side, research on understanding the mechanisms for stable lasing in topological systems is ongoing. For example, it is commonly assumed that stable edge state lasing requires the optical gain to be localized to the edge of the system. On the other hand, even though the experiments shown in Fig. 6 employed uniform optical pumping, no lasing of bulk modes was observed. Secl et al. (2021) proposed a mechanism for this surprising observation based on excess gain occurring in the topologically-trivial cladding medium. Research on this topic including the interplay with non-Hermitian topological phenomena remains ongoing.

Making photonic quantum Hall effects quantum

A long-standing challenge has been to integrate topological band structure effects with strong (single photon level) interactions to generate many-body bosonic quantum Hall effects. This is hard because nonlinear optical effects are typically very weak, requiring intricate schemes involving resonant nonlinearities (Imamoğlu et al., 1997), ultra-high quality factor cavities, and pumping to compensate for losses. Comprehensive reviews on this subject and the quantum simulation of other strong interaction phenomena using photons are given by Noh and Angelakis (2016) and Carusotto et al. (2020).

Theoretical proposals

Early works proposed bosonic analogues of fractional quantum Hall states using atoms trapped in optical lattices and cavity arrays, using modulated couplings to induce effective magnetic fields for neutral particles (Sørensen et al., 2005; Hafezi et al., 2007; Cho et al., 2008; Hayward et al., 2012). These proposals were then generalized to photonic systems with strong photon-photon interactions (Koch et al., 2010; Nunnenkamp et al., 2011; Umucalılar and Carusotto, 2011; Hafezi et al., 2011).

An important question specific to the photonic schemes is how to reliably generate (fractional) quantum Hall states. Early proposals predicted that in the presence of strong interactions and sufficiently weak losses, two-photon Laughlin states of light could be excited using a coherent pump tuned to the state's energy (Umucalılar and Carusotto, 2012; Hafezi et al., 2013; Umucalılar et al., 2014).

However, uniform driving approaches cannot be easily scaled to larger systems where topological robustness is expected to emerge due to inevitable losses. Losses lead to spectral broadening of the modes, resulting in excitation of multiple modes in larger systems. Moreover, higher photon number states will be exponentially suppressed by losses. Subsequent studies proposed solutions based on two-photon driving designed to restore lost photons (Kapit et al., 2014), and local driving combined with topological pumping Grusdt et al. (2014).

Experiments

Experimentally, strong single photon-level interactions have been demonstrated at microwave frequencies using superconducting qubits (Chen et al., 2014) and at optical frequencies using Rydberg atoms (Firstenberg et al., 2013). In both these platforms, the main difficulty is to maintain the strong interactions while scaling up the system size and number of particles, while using fine-tuning to compensate for and minimize inevitable disorder effects.

Roushan et al. (2017a) were the first to combine strong interactions with a synthetic magnetic field using the three-site lattice of superconducting microwave qubits shown in Fig. 7A, observing a photon number-dependent chirality of the dynamics. Subsequent

Fig. 7 Experimental platforms for many-body bosonic quantum Hall effects. (A) Superconducting transmon qubits Q_i connected via adjustable couplers CP_{ij} which are periodically modulated in time to induce an effective magnetic flux. (B) Array of superconducting transmon qubits, where two-photon driving combined with coupling to a lossy auxiliary resonator reservoir is used to stabilize a photonic Mott insulator. (C) Twisted four-mirror optical cavity used to generate photonic Landau levels, with strong photon-photon interactions mediated using trapped Rydberg atoms (inset). (A) Modified from Roushan P et al. (2017a) Chiral ground-state currents of interacting photons in a synthetic magnetic field. *Nature Physics* 13(2): 146–151. (B) Modified from Ma R, Saxberg B, Owens C, Leung N, Lu Y, Simon J, and Schuster DI (2019a) A dissipatively stabilized Mott insulator of photons. *Nature* 566(7742): 51–57. (C) Modified from Clark LW, Schine N, Baum C, Jia N, and Simon J (2020) Observation of Laughlin states made of light. *Nature* 582(7810): 41–45.

work observed a Hofstadter butterfly spectrum in a quasiperiodically-modulated one-dimensional lattice (Roushan et al., 2017b). Ma et al. (2019a) implemented two-photon driving to prepare a Mott insulator state of photons in the eight-site lattice shown in Fig. 7B. Implementation of fractional quantum Hall states in this platform remains an outstanding challenge, requiring the combination of a two-dimensional lattice geometry with precise control over the qubit couplings and frequencies.

Parallel efforts targeted at optical frequencies started by generating a continuum Landau level spectrum for photons using the twisted ring resonator (Schine et al., 2016) shown in Fig. 7C. This platform can be combined with strong single photon-level interactions by placing ultra-cold Rydberg atoms within the resonator (Clark et al., 2019), enabling generation of two-photon Laughlin states of light (Clark et al., 2020), detected by measuring angular two-photon correlations. Future work aims to combine this platform with dissipative preparation schemes to assemble many-body quantum Hall states of light.

Conclusion

Over the past decade the emulation of topological phenomena in condensed matter physics including quantum Hall effects has captured the imagination of researchers in photonics. In this Chapter we have attempted to provide a broad overview of this active and still-developing field from its early origins up to topics of ongoing research. While it remains unclear as to whether photonic quantum Hall effects will remain a curiosity among researchers or will form the basis for new and improved devices, there is no doubt that this elegant formalism completes the band theory describing periodic photonic media including photonic crystals (Joannopoulos et al., 2008).

There are numerous future directions for research. On the fundamental side, there are ongoing efforts towards understanding the properties of recently-discovered topological phenomena including higher-order topological phases, topological defect modes, non-Hermitian topological phases, and the role of topology in nonlinear and strongly-interacting systems, as well as observing these phenomena in experiments. At the same time, one (valid) criticism of the ongoing tremendous interest in topological photonic systems is that they are exotica; a solution in search of a problem. Existing approaches towards generating photonic quantum Hall effects have been largely based on clever and intricate designs. To realize the dream of useful device applications we need to develop new approaches to achieve improved figures of merit compared to conventional design approaches.

Photonic quantum Hall effects are one of many examples of how ideas from other research fields can inspire new approaches towards the design and understanding of photonic systems. It is natural to ask where the next big inspiration will come from. One leading candidate is machine learning, a topic which has seen tremendous progress over the past decade and has now started to capture the attention of physicists (Carleo et al., 2019). Not only can ideas from machine learning be applied towards analysis of photonic systems, but concepts from topological photonics might be useful as a means for designing photonic hardware for machine learning including neuromorphic computing (Tan, 2021) and image processing (Zhang and Zhang, 2019; Zhu et al., 2019, 2021) with ultrafast speed and low energy consumption.

Abstract

This article reviews the main contributions to the anomalous Hall effect and its resurgence in the past three decades, which has been accompanied by the rise of topological phenomena and topological materials. I will show that the anomalous Hall effect stems from the interplay of magnetism, spin-orbit coupling, disorder scattering and driving electric fields, it spans the classical, quantum and relativistic worlds, and has generated controversy for nearly one and a half centuries. It has become the smoking gun for detecting magnetic order and, extraordinarily, it continues to reveal new physics, with several novel varieties reported in the past decade.

Key points

- Review experimental and theoretical work on the anomalous Hall effect.
- Elucidate the vital role played by the spin-orbit interaction.
- Demonstrate the interplay of topological quantities and scattering processes.
- Outline new developments in topological materials.

Introduction

In 1879 Edwin Hall discovered the effect that bears his name (Hall, 1879). When a non-ferromagnetic metallic sample is exposed to a perpendicular external magnetic field B , the Lorentz force acting on the current carriers gives rise to a transverse voltage in the plane of the sample. The transverse component of the resistivity, ρ_{xy} , depends on the magnetic field through the relationship $\rho_{xy} = R_0 B$, where $R_0 = 1/(ne)$ is known as the Hall coefficient, n is the carrier density, and $-e$ is the electron charge. This phenomenon, whose explanation is entirely classical, is known as the ordinary Hall effect and is well understood. Determining the Hall coefficient R_0 has become the tool of choice for measuring carrier densities in conducting materials.

The following year Hall noticed that in many ferromagnets the transverse resistivity acquires an additional term independent of the magnetic field, which is often proportional to the magnetization M of the sample, and becomes constant once the sample has reached its saturation magnetization (Hall, 1881). The effect is referred to as the anomalous Hall effect (AHE). Whereas the ordinary Hall effect of classical physics requires an external magnetic field, the anomalous Hall effect requires only a magnetization, and it was soon realized that ferromagnets display a spontaneous Hall conductivity in the absence of an external magnetic field. The effect has been subsequently observed in a multitude of systems, including transition metals and their oxides, in materials which exhibit colossal magnetoresistance, ferromagnetic semiconductors, topological insulators and a host of other topological materials (Nagaosa et al., 2010).

The anomalous Hall effect stems from the fact that, when a current passes through a magnetic material, electrons are predominantly deflected in one direction. This results in an additional current perpendicular to the driving current, which vanishes if the material is non-magnetic. The mechanisms responsible for this deflection have been the subject of substantial controversy ever since Hall's experimental work. Whereas several mechanisms are known to be responsible, the principal actors are united by the spin-orbit interaction—magnetism by itself is usually not sufficient to give rise to an anomalous Hall current. Furthermore, spin-orbit coupling effects are conventionally divided into intrinsic processes, stemming from a material's band structure, and extrinsic processes, related to scattering events. Recent research has shown that intrinsic spin-orbit coupling effects are intertwined with the topological properties of a material's band structure, and that the interplay of intrinsic and extrinsic processes is highly non-trivial.

This review attempts to present a unified picture of our current understanding of the anomalous Hall effect, of its rich history, and of the tremendous excitement generated by developments over the past two decades. I will begin with a brief historical overview focusing on experimental results and on the theoretical controversy that emerged in the 1950s concerning the relative roles of intrinsic and extrinsic processes in the steady state established in an electric field. I will then cover the key physical aspects of the effect: a brief review of ferromagnetism and inhomogeneous magnetic textures, followed by a discussion of the spin-orbit interaction and its manifestation in the solid state, topological materials, semiclassical dynamics and the quantum kinetic equation, band structure spin-orbit coupling and the topological contribution to the anomalous Hall effect, the role of scalar scattering, and the effect of spin-orbit coupling on scattering potentials leading to skew scattering and side jump scattering. Next I will discuss modern developments in the field, spanning the last 20 years, including the quantized anomalous Hall effect in topological insulators, the distinct roles of bulk and edge transport in topological materials, the planar Hall effect and its offshoots, and the non-linear anomalous Hall effect. I will end with a brief summary and discussion of future directions.

Overview

The anomalous Hall effect has a lengthy and controversial history and remains incompletely understood. At its heart lie the physical concepts of ferromagnetism and spin-orbit coupling, on which I will concentrate in the next section. To facilitate the exposition I will identify a *Classic Period*, spanning the time from the discovery of the anomalous Hall effect to the last decade of the twentieth century, and a *Modern Era* spanning the last decade of the twentieth century and the first decade of the twenty-first, and a *Topological Era*, from the rise of topological materials to the present day. The Classic Period was characterized by initial experimental observations followed by a lengthy fundamental debate, and we can place its end approximately after the discovery of the quantum Hall effects. The Modern Period has been characterized by a surge in interest in topological quantities and a persistent effort to understand the parameter ranges in which different mechanisms dominate. The Topological Period has been shaped by the discovery of topological materials and the emergence of a variety of new anomalous Hall effects.

Classic Period. Following Hall's original work, experiments focused on the anomalous Hall effect in transition metals, and on its exact relationship to the magnetization M . It was determined empirically that the Hall resistivity follows the relationship $\rho_{xy} = R_0 B + R_s M$, with the constant R_s referred to as the anomalous Hall coefficient (Pugh and Lippert, 1932). Frequently $R_s \gg R_0$ (Pugh et al., 1950). It was established that a spontaneous Hall current indeed exists in the absence of a magnetic field, as shown in Fig. 1. In due course this spontaneous current became the smoking gun for the identification of ferromagnetic order, considering that such a transport test is much easier to perform experimentally than optical techniques based on dichroism or on the Kerr and Faraday effects.

The controversy surrounding the origins of the anomalous Hall effect began after decades of experimental work. The theory of the AHE was pioneered by Karplus and Luttinger in the 1950s (Karplus and Luttinger, 1954), who found that the spin splitting of bands can give rise to a Hall conductivity in the presence of spin-orbit coupling, identifying a contribution to the AHE which was independent of scattering, or intrinsic. The controversy emerged when Smit countered that in a perfectly periodic lattice the AHE

Fig. 1 Hall electromotive force as a function of the applied magnetic field in a Ni sample which has reached its saturation magnetization. The slope of the lines gives the ordinary Hall coefficient while the y-intercepts give the anomalous Hall coefficients. Fig. 2 Skew scattering. Spin-up and spin-down electrons are scattered preferentially in different directions.

could not occur without scattering from impurities (Smit, 1955). To explain the AHE Smit introduced the extrinsic skew scattering mechanism, which consists of asymmetric scattering of up and down spins by an impurity potential modified by the spin-orbit interaction: an electron is scattered at an angle to its original direction, while spin-up electrons are predominantly scattered in one direction, and spin-down electrons are predominantly scattered in the other. This is illustrated in Fig. 2. Note that spin-orbit coupling is vital in Smit's argument as well: although magnetic impurities cause up and down spins to be scattered in different directions, they will not give AHE by themselves. In response to Smit, in a more complete treatment Luttinger found a term corresponding to skew scattering, which depends on the details of the scattering potential, but maintained that the scattering free contribution to the AHE remains (Luttinger and Kohn, 1955; Kohn and Luttinger, 1957; Luttinger, 1958; Luttinger and Kohn, 1958; Adams and Blount, 1959).

Luttinger's finding was revolutionary, since transport effects known at the time relied on scattering to establish a steady state and give rise to dissipation: both the longitudinal resistivity and the ordinary Hall resistivity depend on scattering. It touched on a fundamental point: the Hall conductivity itself can be non-dissipative, even though for a Hall effect linear in the electric field to occur time reversal needs to be broken, which in the AHE is accomplished by the presence of magnetic order. This can be seen if we think of power dissipation as $\vec{F} \cdot \vec{v}$, the scalar product of the external force with the net velocity. The force in this case comes from the electric field, so that the scalar product vanishes for velocity components transverse to the electric field. The only constraint on the Hall response is the Onsager relation, which states that the transverse conductivity $\sigma_{xy}(\vec{B}) = \sigma_{yx}(-\vec{B})$, or if only a magnetisation is present $\sigma_{xy}(\vec{M}) = \sigma_{yx}(-\vec{M})$. The transverse resistivity likewise satisfies $\rho_{xy}(\vec{M}) = \rho_{yx}(-\vec{M})$.

The skew scattering mechanism introduced by Smit gives a contribution to ρ_{xy} which is proportional to ρ_{xx} , the longitudinal resistivity. Later, a new mechanism, called the side jump was introduced by Berger to explain the observed $\rho_{xy} \propto \rho_{xx}^2$ dependence in certain parameter regimes, to be elaborated below (Berger, 1970). Side jump represents a transverse shift in a wave-packet's center of mass in the course of scattering, which is also asymmetric between spin up and spin down, as shown in Fig. 3. The electron incident into the area of influence of the potential emerges parallel to its original direction but displaced perpendicular to it. The side jump has become the source of much debate, including confusion in terminology (Lyo and Holstein, 1972; Nozieres and Lewiner, 1973; Chazalviel, 1975; Sinitsyn, 2008). The subtle discussion surrounding the side-jump is covered extensively in Nagaosa et al. (2010). Complicating matters is the fact that the intrinsic mechanism leads to the same $\rho_{xy} \propto \rho_{xx}^2$ dependence as Berger's side jump.

Modern Period. One fundamental insight of modern research into the AHE is that the intrinsic, scattering-free contribution of Luttinger and Karplus is related to the Berry curvature of Bloch electrons. It is associated with a deflection of particle trajectories under the action of the spin-orbit interaction in the band structure of the material. This insight first emerged from semi-classical analyses of wave-packet dynamics and has been confirmed by rigorous derivations based on the Kubo formula and the density matrix. At the same time, it is now understood that skew scattering and side-jump, which were originally introduced for electrons with a scalar dispersion scattering off a spin-dependent potential, are qualitatively similar for electrons with spin-dependent dispersions in the presence of scalar potentials.

Much of the recent work has focused on transition metals and transition metal oxides, some of which are itinerant ferromagnets. An important aim has been elucidating the roles of distinct AHE contributions in different parameter regimes, since it is understood that in principle all mechanisms are present concomitantly, and two types of contributions exist which have different dependencies on ρ_{xx} and therefore on the scattering time τ . Three resistivity regimes have been identified: a high mobility regime in which skew scattering dominates because τ is large (Majumdar and Berger, 1973), a good metal regime in which the dominant contribution is

Fig. 3 Side-jump. Spin-up and spin-down electrons undergo a lateral shift in different directions during a scattering process.

Fig. 4 Spin chirality, as illustrated in Nagaosa et al. (2010). An electron spin circulated around three local spins, with which it interacts via exchange coupling, feels the effect of a fictitious magnetic field, whose magnitude is determined by the solid angle subtended by the local spins. From Nagaosa N et al. (2010) Anomalous Hall effect. *Reviews of Modern Physics* **82**: 1539.

independent of τ (Miyasato et al., 2007), and may be intrinsic or side-jump or both, and a low-mobility regime where conduction occurs primarily by hopping, where the overall picture remains unclear (Nagaosa et al., 2010).

Considerable attention was devoted in the 2000s to ferromagnetic semiconductors, which are III–V semiconductors doped with transition metals, the textbook case being (Ga, Mn)As (Jungwirth et al., 2006). Ferromagnetism is mediated by the delocalized conduction holes through the Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction. It was established early on that the scattering-independent contribution $\rho_{xy} \propto \rho_{xx}^2$ dominates the AHE, and nowadays it is strongly believed the intrinsic contribution is responsible. This topological contribution was evaluated for (Ga, Mn)As with magnetic interactions accounted for in a mean field theory, yielding excellent agreement with experiments (Jungwirth et al., 2002). Yet interest in ferromagnetic semiconductors dipped when avenues for pushing the critical temperature to room temperature appeared to be exhausted.

Additional developments in AHE paralleled developments in magnetic materials, notably the discovery of giant and colossal magneto-resistances. Much of the work in this direction has been on complex oxide ferromagnets, and has revealed a novel AHE mechanism termed spin chirality, which also has a geometrical origin, associated with the real-space magnetic texture (Matl et al., 1998). This is shown in Fig. 4. It occurs in manganites, in which transport mainly involves electrons hopping between Mn sites, which leads to colossal magneto-resistance. An electron spin hopping between three or more Mn sites with non-coplanar spin orientations acquires a geometric phase, which can be regarded as stemming from a fictitious magnetic field with magnitude determined by the solid angle subtended by the localized spins. This fictitious magnetic field is coupled to the magnetization through the spin-orbit interaction, and this coupling leads to an anomalous Hall current. A realization of such an inhomogeneous magnetic texture is a topological defect called a skyrmion, and spin chirality reflects an excess of e.g., positive skyrmions over negative skyrmions at finite temperature. The spin chirality mechanism can thus be related to a Berry phase acquired in real space (Ye et al., 1999; Lyanda-Geller et al., 2001). It also leads to an anomalous Hall effect in antiferromagnets (Shindou and Nagaosa, 2001). Spin chirality may occur in the ground state of pyrochlore ferromagnets under the influence of anisotropy, frustration and spin fluctuations but experimental results are inconclusive (Ohgushi et al., 2000; Onoda and Nagaosa, 2003a, 2003b). Indeed the AHE remains poorly understood in many classes of materials with complex spin structures, such as spin glasses with random order, MnSi with spiral spin order, spinels and Heusler alloys.

Topological Period. The last 15 years have been shaped by the rise of topological materials, including topological insulators, Weyl semimetals, transition metal dichalcogenides, and van der Waals heterostructures. The band structures of many of these materials are reminiscent of relativistic dispersions with non-trivial topological structures, and they possess complex surface and edge states. The materials are often quite dirty, making disorder effects important. Topological materials have brought with them a new understanding of the AHE. It was shown that the anomalous Hall effect can be quantized in undoped topological insulators and Weyl semimetals, and it can switch sign in doped topological insulators. In transition metal dichalcogenides the AHE has different signs in the two valleys, leading to a valley Hall effect. Most recently, non-linear and planar versions of the anomalous Hall effect have been identified. The AHE in topological materials is one of the most vibrant research areas today.

Key issues

A very brief picture of ferromagnetism

Since the AHE occurs in ferromagnets, understanding it requires a succinct review of a few key concepts. Ferromagnetism is a consequence of the Coulomb interaction and the Pauli exclusion principle and is intimately connected with the notion of exchange. Based on their relative spin orientations, two electrons can be in either a singlet or a triplet state. The singlet is spatially symmetric and spin anti-symmetric, while the triplet is spin symmetric and spatially anti-symmetric. Due to their different spatial configurations the singlet and triplet states are split by an energy referred to as the exchange energy J , which takes the form

$$J = \int d^3r \phi^*(\vec{r}_1) \psi^*(\vec{r}_2) V_{ee}(\vec{r}_2) \psi(\vec{r}_2) \phi(\vec{r}_1), \quad (1)$$

where ϕ, ψ are the two spatial wave functions, V_{ee} is the Coulomb interaction and (1), (2) denote the two electrons. J may have either sign. In the convention used here positive exchange leads to a triplet ground state. In terms of spin operators this interaction may be written as $H_{2e} = -J \vec{S}_1 \cdot \vec{S}_2$. For an array of atoms interacting via exchange the above Hamiltonian is generalised to the Heisenberg Hamiltonian, appropriate to some insulating systems.

$$H_{He} = - \sum_{ij} J_{ij} \vec{S}_i \cdot \vec{S}_j. \quad (2)$$

Very often the parameters J_{ij} are approximated by a single exchange constant J . It is easily checked that the ground state of the Heisenberg Hamiltonian with positive exchange has all spins pointing in the same direction. The system has the freedom to choose the direction, and when it does so both time reversal and rotational symmetry are broken.

Exchange leads to magnetic order in many different forms, and the situation in real materials is far more complex than the above. For example, magnetism in manganites is mediated by double exchange, which involves different atomic orbitals, while magnetism in spinels occurs due to super-exchange, which involves an intermediate atom. Ferromagnetism can also leak from one material into another material adjacent to it via a ferromagnetic proximity effect.

Conducting ferromagnets are often itinerant, with a notable example being provided by ferromagnetic semiconductors (Dietl et al., 2001). In the simplest picture, a local Mn moment interacts with an itinerant hole. That interaction is in fact anti-ferromagnetic, so their spins tend to align anti-parallel to each other. The hole, being delocalized, travels through the sample and interacts anti-ferromagnetically with a second local Mn moment. The hole thus mediates an interaction between the two local moments, which end up aligning parallel to each other, so the net interaction between them is ferromagnetic. This is the basis of the Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction. In topological insulators doped with ferromagnetic ions the situation is similar in spirit except magnetism is mediated by band electrons through the van Vleck mechanism. These electrons may reside in the valence band and the mechanism is active even when the system is insulating.

Due to the complexity of a fully quantum mechanical description in terms of spin operators, magnetism is most often thought of in a *mean field* picture. Each spin is assumed to interact with the net effective magnetization M produced by all the other spins. For itinerant ferromagnets the simplest theory is the Stoner description, which considers the charge carriers to be quasiparticles in spontaneously split bands. Thus a spin travelling through a ferromagnetic material interacts with the average magnetization, while fluctuations in the magnetization play an analogous role to spin-dependent scattering off an impurity.

In general the magnetization $\vec{M} = \vec{M}(\vec{r})$ is inhomogeneous and has a strong position dependence. Real samples are fragmented into domains, whose magnetizations point in different directions, and which are separated by domain walls. Magnetizations can vary in space in other ways, exhibiting topological defects referred to as skyrmions, which are akin to vortices (Göbel et al., 2001). An example of a magnetic skyrmion is shown in Fig. 5. These are prominent in correlated oxides and dilute magnetic semiconductors. Magnetic skyrmions are small swirling topological magnetic excitations with particle-like properties, in which the spin at the core and the spin at the perimeter point in opposite directions. They result from the competition between the Dzyaloshinskii-Moriya and exchange interactions, and give rise to a nonzero Berry curvature in real space, which plays the role of an effective or *emergent* magnetic field, and can reach the equivalent of thousands of Teslas in very small skyrmions, that is, smaller than 10 nm. This emergent magnetic field deflects conduction electrons and causes a topological Hall effect, a relative of the anomalous Hall effect that does involve neither a magnetic field nor spin-orbit coupling (Bruno et al., 2004). At the same time the formation of magnetic skyrmions reduces an average magnetization and makes it somewhat challenging experimentally to differentiate the topological Hall effect from the anomalous Hall effect.

The simplest textbook models tend to assume tacitly that the temperature is absolute zero. Ferromagnetism occurs below the Curie temperature T_c . The critical temperature at which ferromagnetism occurs is determined by a number of parameters, including the exchange and the size of the ionic spins. As ferromagnetism vanishes above T_c the anomalous Hall effect vanishes with it, making it a useful tool for measuring the transition temperature. Below T_c several temperature-dependent mechanisms come into play, including the temperature-dependence of the magnetisation, which dominates in SrRuO₃ (Allen et al., 1996; Izumi et al., 1997; Fang et al., 2003), the variation of scattering times with temperature and contributions from spin waves. Their interplay makes the AHE temperature dependence exceedingly complex, and it remains an active research area.

Fig. 5 An example of a magnetic skyrmion. From Göbel B, Mertig I and Tretiakov OA (2001) Beyond skyrmions: Review and perspectives of alternative magnetic quasiparticles. *Physics Reports* 895: 1.

Spin-orbit coupling

At the heart of the anomalous Hall effect lies the spin-orbit interaction. Since all contributions to AHE are traced back to spin-orbit coupling, we shall discuss this interaction and its consequences for transport in solid state systems in some detail. The spin-orbit interaction appears in quantum mechanics as a relativistic effect, emerging explicitly when one transitions from the Dirac equation to the Pauli equation. For free electrons with charge $-e$ a natural separation of energy scales can be made into small terms (momentum) and large terms (mass), which leads to a decomposition of the resulting Hamiltonian into the kinetic energy, the electrostatic potential contribution eV , the Zeeman term and spin-orbit coupling, which takes the form: (Messiah, 2014)

$$H_{SO} = \frac{\hbar}{4m^2c^2} \vec{\sigma} \cdot \vec{\nabla} V \times \vec{p}. \quad (3)$$

The potential V is the full potential acting on the electron. For a free electron the spin-orbit interaction is typically negligible. In an atom $\vec{\nabla} V$ is the central potential and the spin-orbit interaction is $\propto \vec{L} \cdot \vec{S}$, where $\vec{L}$ denotes the orbital angular momentum and $\vec{S}$ the electron spin, which accounts for the name of the interaction. Atomic spin-orbit coupling can be very strong and, since the atomic potential appears in Eq. (3), it is clear that the spin-orbit coupling increases with atomic number and becomes stronger as one advances down the periodic table.

For electrons in a crystal V contains: (i) an *intrinsic* contribution arising from the periodic potential and applied electric fields, the latter encompassing both electrostatic gates and driving electric fields; and (ii) an *extrinsic* contribution from the random disorder potential and phonons.

In the effective mass picture the overall form of the band structure spin-orbit interaction around a particular band extremum can be determined from symmetry considerations. To obtain the relevant pre-factors one typically adds the spin-orbit term of Eq. (3) to the general crystal Hamiltonian and projects out bands until we find an effective model for the bands of interest, which tend to be the conduction band or the valence band. It is worth noting the similarity between Eq. (3) and the Zeeman effect. To understand we recall that electrons in the conduction bands of many materials behave as quasiparticles with an effective spin-1/2, in other words their behavior is very similar to that of free electrons. As a consequence, the intrinsic band-structure contribution to the spin-orbit interaction is very similar to that for free electrons. It can be represented as the interaction between the spin and a momentum-dependent effective Zeeman field whose form is determined by the symmetry of the crystal. This effective field is odd in momentum and integrates to zero over the crystal since spin-orbit coupling does not break time-reversal. For terms odd in the momentum to be allowed the structure must break inversion symmetry. In 3D the crystal itself must break inversion symmetry, a property known as bulk inversion asymmetry (BIA). To describe the spin-orbit interaction in confined systems one needs to add the confinement potential. Confinement to 2D can be modelled analytically by a square or parabolic well for the symmetric case, or by a triangular well for the asymmetric case, and by more sophisticated Schrodinger-Poisson methods when electron-electron interactions need to be taken into account. In the context of Eq. (3), gate fields are usually taken into account within the device confinement model, while driving electric fields, and their accompanying spin-orbit effects, are treated perturbatively, most often within a linear-response framework. In a 2D structure an additional spin-orbit mechanism is present. For an effective spin-1/2 such interactions have the general form of Eq. (3), with the pre-factor replaced by a material- and structure-specific parameter. In a 2D electron gas we need to consider the contribution from the confinement potential, which generates an electric field along the z -direction perpendicular to the interface, so that, setting $\vec{\nabla} V \parallel \hat{z}$ in Eq. (3), we obtain the well-known Rashba interaction (Bychkov and Rashba, 1984),

$$H_R = \alpha (\sigma_x k_y - \sigma_y k_x). \quad (4)$$

Spin-orbit coupling provides a wave vector-dependent quantization direction for the charge carriers' spins. For the Rashba interaction to be nonzero the 2D electron gas needs to be asymmetric, a feature referred to as structure inversion asymmetry (SIA). It increases linearly with the gate electric field for known electron systems.

In analogy with the Rashba interaction, the spin-orbit interaction for electron systems in conducting materials can very frequently be written in the form $\vec{\sigma} \cdot \vec{B}_k$, where $\vec{B}_k$ can be thought of as an effective magnetic field that depends on the electron momentum (Winkler, 2003). This picture, which remains very common, is intimately linked to one of the main spin relaxation mechanisms in conductors, the Dyakonov-Perel mechanism (D'yakonov and Perel, 1971; Pikus and Titkov, 1984). The spin-orbit interaction in these materials is accompanied by the scalar kinetic energy $H_{kin} = \frac{\hbar^2 k^2}{2m}$, which is much larger than it. The total Hamiltonian has two eigenstates which correspond to two spin-split sub-bands. The spin precesses between scattering events under the action of the band structure spin-orbit effective field $\vec{B}_k$. During ordinary scalar scattering events, the wave vector changes from $\vec{k}$ to $\vec{k}'$, and the spin now precesses about a different field $\vec{B}_{k'}$. If the scattering rate is much larger than the precession frequency the spin does not have time to precess between scattering events and preserves its orientation, leading to the counter-intuitive conclusion that more momentum scattering increases the spin lifetime. If we associate momentum scattering with a relaxation time τ , the product $\vec{B}_k \tau / \hbar$, with $\vec{k}$ usually evaluated at the Fermi energy, determines two qualitatively different regimes. The

Dyakonov-Perel regime corresponds to $\frac{\vec{B}_k \tau}{\hbar} \ll 1$, while in the weak scattering regime $\frac{\vec{B}_k \tau}{\hbar} \gg 1$, and momentum scattering leads to a reduction in the spin lifetime. In the past, especially at the time of the debate between Luttinger, Smit and Berger, the Dyakonov-Perel regime was the only experimentally accessible regime. Whether referring explicitly to spin relaxation or not, early calculations of the anomalous Hall effect almost invariably assumed the Dyakonov-Perel regime. In the past two decades, as a result of substantial increases in sample quality, the weak scattering regime is routinely accessed.

Another contribution to the potential in Eq. (3) is the random disorder potential $U(\vec{r})$, which, in momentum space, gives rise to the following term, which causes spin-dependent scattering:

$$H_{ss} = -i \lambda U_{\vec{k}\vec{k}'} \vec{\sigma} \cdot \vec{k} \times \vec{k}'. \quad (5)$$

It can be thought of as a random effective magnetic field, which depends on an electron's incident and scattered wave vectors. In two-dimensional systems, in which $\vec{k}$ and $\vec{k}'$ are both in the plane, the effective magnetic field points out of the plane. In the older literature it was common to associate the additional term in the potential with a fictitious coordinate shift, so that the position operator would be modified from $\vec{r}$ to $\vec{r} + \lambda \vec{\sigma} \times \vec{k}$. When the potential $U(\vec{r})$ becomes $U(\vec{r} + \lambda \vec{\sigma} \times \vec{k})$ and is expanded in λ Eq. (5) emerges (Sinitsyn, 2008).

Skew scattering and side jump are both a consequence of Eq. (5). In skew scattering spin-up electrons are predominantly scattered in one direction, and spin-down electrons in the other. Side jump consists of a transverse displacement of the outgoing electron trajectory with respect to its incoming path, which again has the opposite sign for up and down spins. Eq. (5) is also at the heart of the second most common spin relaxation mechanism, referred to as the Elliott-Yafet mechanism, in which the electron spin flips during scattering events as a result of the λ -dependent term in the potential (Elliott, 1954; Yafet, 1963). This mechanism is important in materials that have a center of inversion, so that $\vec{B}_k = 0$ and there is no spin precession.

Topological materials

Another set of materials in which spin precession is generally absent, albeit for qualitatively different reasons, is that of topological materials. The term topological materials encompasses a broad range of structures that exhibit phases characterized by a topological invariant that remains unchanged by deformations in the system Hamiltonian. This can be the Chern number or the Z_2 invariant, or the discussion can be phrased more generically in terms of the Berry curvature, whose integral over the Brillouin zone yields the Chern number. Topological materials include topological insulators, Weyl and Dirac semimetals, and topological superconductors. The distinction is not always clear cut, since some categories overlap. For example, certain transition metal dichalcogenides can become topological insulators under appropriate circumstances, while others, such as WTe_2 , can be Weyl semimetals.

The surface states of topological insulators are described by the Hamiltonian (Liu et al., 2010):

$$H_{TI} = \hbar v_F (\sigma_x k_y - \sigma_y k_x) + w \sigma_z (k_x^3 - 3k_x k_y^2), \quad (6)$$

where v_F and w are material-specific parameters and σ_i are the Pauli spin matrices. The hexagonal warping term is particularly strong in Bi_2Te_3 . These states reside on opposite surfaces of a three-dimensional slab, yet usually all surfaces have topological states, which in Hall transport in particular mean that current can flow around the edges. The Hamiltonian H_{TI} can be thought of as the limit of the Rashba Hamiltonian without the kinetic energy term $H_{kin} = \frac{\hbar^2 k^2}{2m}$. This distinction is illustrated in Fig. 6. In this case we no longer have a conduction band consisting of two spin-split sub-bands, but the two eigenvalues of the Hamiltonian correspond to the surface conduction and valence bands. Only the surface conduction band crosses the Fermi surface and there can be no spin precession, since that involves the electron switching between two sub-bands. In fact in equilibrium the direction of the momentum fully determines the direction of the spin, which is referred to as spin-momentum locking. For Hamiltonians of the Rashba form, where the spin is transverse to the momentum, spin-momentum locking leads to chirality, as opposed to helicity, which characterizes Hamiltonians of the form $\vec{\sigma} \cdot \vec{k}$, where the spin is parallel or anti-parallel to the momentum. Because of spin-momentum locking, when the wave vector changes in a scattering process the spin also changes, and if the wave vector is reversed the spin must be flipped, which breaks time reversal. It follows that time-reversal invariant perturbations such as charged impurities and phonons cannot lead to back-scattering in topological insulators.

Fig. 6 Effective fields representing the spin-orbit interaction in (A) Rashba semiconductors and (B) topological insulators.

Dirac and Weyl semimetals are different cases of the following Hamiltonian (Armitage et al., 2018)

$$H_{DW} = \hbar v_F \tau_x \vec{\sigma} \cdot \vec{k} + m \tau_z + b \sigma_z + b' \tau_z \sigma_x, \quad (7)$$

where the vector $\vec{\sigma}$ of Pauli spin matrices here represents a pseudo-spin degree of freedom, $\vec{\tau}$ the valleys or nodes, m is a mass parameter, and b and b' are effective Zeeman fields due to various internal degrees of freedom. Dirac semimetals have a single node and correspond to $m = b = b' = 0$, while the simplest model of a Weyl semimetal has two nodes when $|b| > |m|$ and $b' = 0$, that act as source and sink of Berry curvature. Known materials typically possess many pairs of nodes. Weyl semimetals break inversion symmetry or time reversal symmetry or both. The materials that break time reversal tend to have a magnetization built into the system and exhibit an anomalous Hall effect, which will be discussed below.

Transition metal dichalcogenides are described by the Hamiltonian (Xiao et al., 2012):

$$H_{TMD} = \hbar v_F (\tau \sigma_x k_x + \sigma_y k_y) + \frac{\Delta}{2} \sigma_z - \frac{\gamma \tau}{2} (\sigma_z - I) s_z + \frac{\kappa}{2} (\sigma_+ k_+^2 + \sigma_- k_-^2) \quad (8)$$

where s_i represents spin, $\tau = \pm$ is the valley, $\vec{\sigma}$ is an orbital pseudospin index, analogous to the sublattice pseudospin encountered in graphene, I represents the identity matrix in two dimensions, and $\sigma_{\pm} = \sigma_x \pm i \sigma_y$. The spin splitting at the valence band top caused by the spin-orbit coupling is denoted by 2γ . Additional terms encapsulate the spin splitting of the conduction band, the electron-hole asymmetry and the trigonal warping of the spectrum. There is always a gap between the valence and conduction bands, which is manifested in the mass appearing in each of the copies of the Dirac Hamiltonian. Consequently, to satisfy time reversal invariance, the materials have two valleys, which are related by time reversal. The valleys are spin polarized with opposite polarizations. Even when spin-orbit coupling is strong there is no spin precession, but only a tilting of the spin quantization axis.

Charge transport description of the anomalous Hall effect

We are now ready to introduce a dynamical description of the anomalous Hall effect in terms of charge transport under the action of an electric field. Considerable insight can be gleaned from the conceptually simplest transport theory, which consists of the semi-classical model of carrier dynamics combined with the Boltzmann equation. Before discussing the semi-classical model some preliminary considerations are necessary.

In a non-trivial multi-band system, the energy and thus the Hamiltonian of the electron depend not only on the average position of the electron in the crystal but also its wave momentum in the Brillouin Zone. We can regard this as a situation where the Hamiltonian is adiabatically changed via a parameter, in this case the momentum. In quantum mechanics, the wave function acquires a dynamical phase factor due to energetic oscillation of the eigenstates. This has the form $e^{-i\varepsilon_n t/\hbar}$, where ε_n is the energy dispersion of band n . Aside from this, Berry studied the effect of a slowly changing Hamiltonian and found that an additional geometric phase is accumulated, known as the Berry phase (Berry, 1984). The wave function acquires local phases in momentum space, which manifest themselves in the Berry connection $\vec{\mathcal{A}}_n = i \langle u_n | \frac{\partial u_n}{\partial \mathbf{k}} \rangle$, where $|u_n\rangle$ is the lattice-periodic part of the Bloch wave.

The Berry connection $\vec{\mathcal{A}}_n$ is a gauge field, that is, a device to account for the local phases that arise from the band structure. It is gauge-dependent, but the phase acquired by the wave function can also be expressed in terms of the gauge-invariant Berry curvature $\vec{\Omega}_n = \vec{\nabla}_{\mathbf{k}} \times \vec{\mathcal{A}}_n$. This relationship between the Berry connection and Berry curvature is analogous to the one connecting the magnetic vector potential and magnetic field. Therefore, $\vec{\mathcal{A}}_n$ has a gauge freedom arising from the choice of basis, whereas the curvature $\vec{\Omega}_n$ is a gauge invariant physically meaningful quantity. The Berry curvature can be identified with a monopole in momentum space. An alternative way to look at it is by noting that the expectation value of the position operator in Bloch bands contains a term analogous to that for free electrons, plus a correction that depends on the Berry connection. Due to this correction different components of the electron position, when restricted to a single band, do not commute. If we denote the position expectation value in band n by $\vec{R}_n$, then $\vec{R}_n \times \vec{R}_n = \vec{\Omega}_n$, in exact analogy to the non-commutativity of different components of the momentum in the presence of a magnetic field.

The semi-classical model describes the dynamics of wave-packets between scattering events, while the Boltzmann equation, to be discussed in due course, captures the change in occupation induced by electric fields and scattering. A wave packet has a finite width about its center of mass $\vec{r}_n$ in real space, and a finite width in momentum space about its average wave momentum $\vec{k}_n$. The widths in real and momentum space must be consistent with the uncertainty principle. The wave packet starts in a band n and is assumed to remain in this band. The wave momentum and position evolve in time according to the semiclassical equations of motion (Sundaram and Niu, 1999):

$$\hbar \dot{\vec{k}}_n = -e \left(\vec{E} + \dot{\vec{r}}_n \times \vec{B} \right) \quad (9)$$

$$\hbar \dot{\vec{r}}_n = \frac{\partial \varepsilon_n}{\partial \vec{k}} - \hbar \dot{\vec{k}}_n \times \vec{\Omega}_n. \quad (10)$$

and $\vec{\Omega}_n$, as above, is the Berry curvature. The first equation is familiar: it simply encapsulates the combined effect of the electrostatic force and the Lorentz force acting on the electron. The second equation shows that the geometric phase must be taken into account

in calculating the velocity of a wave packet through the Berry curvature term $\vec{\Omega}_n$. With this term the equations for the velocity and acceleration look similar, where the Berry curvature is analogous to a magnetic field defined in momentum space. In the systems we are interested in the Berry curvature usually arises from band structure spin-orbit coupling. Importantly, if we turn off the magnetic field the second equation simplifies to

$$\hbar \vec{v}_n = \frac{\partial \varepsilon_n}{\partial \vec{k}} + e\vec{E} \times \vec{\Omega}_n. \quad (11)$$

The second term represents a sideways displacement of charge carriers even in the absence of scattering. This displacement is responsible for a transverse current, in other words a Hall effect, and since there is no magnetic field this is an anomalous Hall effect. Given that the change in the wave packet position is already first order in the electric field the expectation value of the current involves only the equilibrium distribution, i.e., the Fermi-Dirac function. Scattering does not enter this expression. This is the intrinsic topological contribution to the AHE (Onoda and Nagaosa, 2002).

Let us examine the symmetry considerations for the Berry curvature and for its integral over filled states. The semiclassical equations must be invariant under time reversal, therefore $\vec{\Omega}_n$ must be odd under this transformation, $\vec{\Omega}_n(-\vec{k}) = -\vec{\Omega}_n(\vec{k})$. A geometric argument can also be made by noting that the Berry phase is a path dependent quantity. Under time reversal, both the path along which the wavefunction is transported and the orientation of the wave vector $\vec{k}$ are reversed. A clockwise path spanning a set of wave vectors $\vec{k}$ becomes an anticlockwise path spanning the set of wave vectors $-\vec{k}$. This implies that the Berry phase changes sign under time reversal and the Berry curvature satisfies the above constraint.

If time reversal symmetry is present, Kramers degeneracy must also be present, imposing $\varepsilon_n(\vec{k}) = \varepsilon_n(-\vec{k})$. Therefore, if the state at wave vector $\vec{k}$ is occupied then so is the state at wavevector $-\vec{k}$. This, together with the condition $\vec{\Omega}_n(-\vec{k}) = -\vec{\Omega}_n(\vec{k})$ implies that the integral of $\vec{\Omega}_n(\vec{k})$ over all filled states vanishes. Therefore, in general it is always necessary for the system to lack time reversal symmetry in order for the AHE to occur. This requirement is fulfilled by the magnetisation. In the systems we are interested in the Berry curvature usually arises from the band structure spin-orbit coupling. Therefore the interplay of band structure spin-orbit interaction, adiabatic change in the wave vector in the external electric field, and out-of-plane magnetization leads to a nonzero AHE through the Berry curvature. We can think of the effect as a dynamical process. A driving electric field accelerates the electron, changing its momentum, and from Eq. (3) it is apparent that a change in momentum results in a spin rotation. The spin rotation in turn causes a change in the wave vector, and this change results in a displacement transverse to the original direction, leading to a Hall current. We can take as an example a two-dimensional system spanning the xy -plane with a Hamiltonian of the form

$$H_{2D} = \frac{\hbar^2 (k_x^2 + k_y^2)}{2m} + \alpha (\sigma_x k_y - \sigma_y k_x) + M\sigma_z, \quad (12)$$

where M is the perpendicular magnetisation (Culcer et al., 2003). The dispersion is sketched in Fig. 7 and the Berry curvature in Fig. 8. The intrinsic anomalous Hall conductivity takes the form

$$\sigma_{xy} = -\frac{e^2}{h} \int \frac{d^2 k}{2\pi} \sum_n f_{FD}^n \Omega_{n,z}, \quad (13)$$

where f_{FD}^n is the Fermi-Dirac distribution for band n and $\Omega_{n,z}$ is the z -component of the Berry curvature of the band. If conduction involves more than one band or sub-band one needs to sum over all n . The Fermi-Dirac function ensures this term in the conductivity contains an integral over filled states, hence it originates from the entire Fermi sea. At zero temperature, when the Fermi-Dirac distribution is a Heaviside function the conductivity is given by the integral of the Berry curvature over occupied states. Formally the conductivity will be quantized if the integral involves one band and covers the entire Brillouin zone. The integral of the Berry curvature over the Brillouin Zone is referred to as the Chern number. This is a topological invariant, meaning that

Fig. 7 Energy dispersion as a function of wave vector for the model of Eq. (12). The chemical potential μ in this example has been placed in the gap between the spin-split sub-bands opened by the magnetization. Fig. 8 Berry curvature as a function of wave vector for Eq. (12). Adapted from Culcer D, MacDonald AH and Niu Q (2003) Anomalous Hall effect in paramagnetic two-dimensional systems. *Physical Review B* **68**: 045327.

perturbations to the bands do not change it unless the band structure is re-ordered and band crossing points are created or destroyed, in which case it changes by an integer.

The quantized value depends on the specifics of the Berry curvature: for the Rashba interaction it is $\frac{1}{2}$. The integral may be close to its quantized value if a single band is occupied and the Fermi wave vector is large enough. Yet it should be noted that in systems in which spin-orbit coupling leads to spin precession, which essentially means all known metal and semiconductor structures, conduction involves at least two spin-split sub-bands. The Berry curvatures of these sub-bands invariably have opposite signs. If the Fermi energy is such that only one sub-band is occupied then the Fermi wave vector tends to be relatively small, so that the integral in Eq. (13) is considerably less than the quantized value. Therefore in systems exhibiting spin precession it is virtually impossible for the topological contribution to the AHE to be quantized. This possibility exists, however, in systems displaying spin-momentum locking, such as topological insulators.

To visualize the connection between a quantum mechanical phase and a conductivity note that the spin orbit interaction couples the spin up and spin down bands. This coupling transfers the time reversal violation from the spin degree of freedom to the orbital motion, which is responsible for the Berry curvature. Spin-orbit coupling provides a wave vector-dependent quantization direction for the spin, so that as the wave vector is displaced the spin is rotated and it is possible to obtain a nonzero Berry curvature. For example, for the Rashba interaction, the spins prefer to lie in the xy -plane and be perpendicular to the wave vector. As a result, when the wave vector sweeps a circle around the origin, the spins are rotated by a solid angle of 2π , and acquire a Berry phase of π . Since this phase is independent of the area enclosed, it follows that the Berry curvature is singular at the origin and is zero everywhere else. A perpendicular magnetization will tilt the spins out of the xy -plane. The amount of tilting depends on the competition between the Rashba term and the magnetization. The solid angle swept by the spins is different from 2π and depends on the size of $\vec{k}$, tending to zero as the radius of the circle tends to zero. This implies that the Berry curvature is now spread out and is finite at the origin.

Disorder contributions to the AHE are exceedingly complex. The full disorder potential is

$$H_{\vec{k}\vec{k}'}^{dis} = U_{\vec{k}\vec{k}'} \left(1 - i \lambda \vec{\sigma} \cdot \vec{k} \times \vec{k}' \right) \quad (14)$$

where the first term represents scalar, spin-independent scattering, due to e.g., Coulomb impurities, roughness, dislocations, and the second term is the spin-orbit correction to it, causing spin-dependent scattering. The disorder potential is a random function, therefore in determining expectation values one deals only with averages over impurity configurations, expressing final results in terms of a parameter quantifying the disorder strength. Here this parameter is chosen to be the impurity density n_i .

We consider first the case when the AHE is purely extrinsic. There is no spin-orbit coupling in the band structure and spin is conserved between scattering events. In this case skew scattering and side jump are captured by the Boltzmann equation. They arise from the spin-dependent part of the scattering potential $\propto \lambda$, as was originally discussed for ferromagnetic metals. We consider as a pedagogical model the simplest example of a 2D system, so that $\vec{k} \times \vec{k}'$ points out of the plane, and $\vec{\sigma} \rightarrow \sigma_z$. In this case one may write down separate Boltzmann equations for the non-equilibrium distributions $f_{\vec{k}s}^- \equiv f_{\vec{k}\uparrow}^-, f_{\vec{k}\downarrow}^-$ for the up and down spins. In a spatially uniform system in the steady state, where the time dependence drops out, these take the form:

$$J(f_{\vec{k}s}^-) = \frac{eE}{\hbar} \cdot \frac{\partial f_{FD,s}}{\partial \vec{k}}. \quad (15)$$

Working to linear order in the electric field, the right hand side contains the equilibrium Fermi-Dirac distribution, which differs for the two spin species only through the presence of the magnetization in the energy. $J(f_{\vec{k}s}^-)$ denotes the scattering term. The leading term in $J(f_{\vec{k}s}^-)$, corresponding to the Born approximation and Fermi's Golden Rule, contains the absolute value $\left| H_{\vec{k}\vec{k}'}^{dis} \right|^2$, whence it is immediately seen that the imaginary, spin-dependent term $\propto \lambda$ drops out when the absolute value is taken. It follows that for a scalar band structure there is no skew scattering in the Born approximation. The expansion in the scattering potential must be

continued up to third order, and the resulting transition rate will be asymmetric in the incident and scattered wave vectors: for any one spin species the amplitude for scattering from $\vec{k}$ to $\vec{k}'$ is not the same as the amplitude for scattering from $\vec{k}'$ to $\vec{k}$, in other words, we have asymmetric scattering of up and down spins.

For $\lambda = 0$ for an isotropic band structure Eq. (15) is easily solved to yield

$$f_{\vec{k}s} = \frac{eE\tau_s}{\hbar} \cdot \frac{\partial f_{FD,s}}{\partial \vec{k}}, \quad (16)$$

where $\tau_s \propto 1/n_i$ is the momentum relaxation time for each spin species. Since the magnetisation is invariably a small fraction of the Fermi energy, $\tau_{\uparrow} \approx \tau_{\downarrow} \approx \tau$, and we may speak of a single momentum relaxation time evaluated at the Fermi surface. The distribution function in this case leads to the familiar Drude term for the conductivity, $\sigma_{xx} \propto \tau$, and the resistivity $\rho_{xx} \propto 1/\tau$. Noting that $\frac{\partial f_{FD}}{\partial k}$ at absolute zero is a delta function at the Fermi energy, the Drude term is due to the electrons at the Fermi surface. For $\lambda \neq 0$ an additional term linear in λ appears in each distribution, with opposite signs for the two spins. There is a difference in the transport of up and down spins, and a full analysis reveals that up spins and down spins are displaced in different directions perpendicular to their direction of travel. The additional, skew scattering, contribution to the conductivity is a Hall term σ_{xy} linear in λ , linear in the magnetisation, proportional to τ , and attributed to the electrons at the Fermi surface.

Experimentally one measures the resistivity rather than the conductivity. Inverting the conductivity tensor we obtain $\rho_{xy} = \frac{\sigma_{xy}}{\sigma_{xx}^2 + \sigma_{xy}^2} \approx \frac{\sigma_{xy}}{\sigma_{xx}^2}$, since $\sigma_{xx} \gg \sigma_{xy}$. For skew scattering the Hall conductivity $\sigma_{xy} \propto \tau$ meaning $\rho_{xy} \propto 1/\tau$ in other words $\rho_{xy} \propto \rho_{xx}$. In contrast, for the intrinsic topological term σ_{xy} is independent of τ , hence $\rho_{xy} \propto 1/\tau^2$ that is $\rho_{xy} \propto \rho_{xx}^2$.

The side-jump term in the AHE appears in the Born approximation provided some modifications are made. To begin with, in Eq. (3) we need to include the contribution to V due to the external electric field, and this gives rise to an additional, spin-dependent term in the interaction of an electron with the field. It is tantamount to a spin- and electric field-dependent modification of the electron energy. Aside from this, in the derivation of Fermi's Golden Rule, the quantum mechanical time evolution operator must include the interaction with the electric field—physically, one must account for the fact that electrons are accelerated by the external field during collisions. Solving the resulting Boltzmann equation including these new terms one finds the side-jump contribution, which is linear in λ , linear in the magnetisation, apparently independent of τ due to the cancellation of terms $\propto \tau$ and $\propto 1/\tau$, and due to the Fermi surface. Being independent of τ it leads to $\rho_{xy} \propto \rho_{xx}^2$ exactly the same as the intrinsic term.

The appearance of disorder terms to order zero in τ is simply a reflection of the fact that (i) the non-equilibrium correction to the electron distribution is an expansion in powers of the disorder strength, which can be cast as an expansion in the parameter $1/\tau$; and (ii) the leading term in this expansion is $\propto \tau$, linear in the transport time that is needed to keep the Fermi surface near equilibrium. The next-to-leading term is thus of order $\tau^0 \rightarrow 1$.

What happens when spin-orbit coupling is present in the band structure, and scattering off impurities is purely scalar? For this we need the full kinetic equation, which is beyond the scope of this review. The main conclusions are as follows. Physically, the combination of band structure spin-orbit coupling and scalar scattering can be understood in the same language as extrinsic spin-orbit scattering: there are contributions to the AHE that can be understood as skew scattering and side-jump. Importantly, in this case the side-jump contribution is of the same order of magnitude as the topological contribution, and for certain models and in certain regimes cancels it altogether (Inoue et al., 2006; Nunner et al., 2007). In the Rashba model of semiconductor nanostructures the AHE cancels altogether when the Fermi energy is deep in the upper sub-band. In doped topological insulators the skew scattering and side-jump terms induced by the band structure spin-orbit coupling ultimately cancel the topological contribution to the AHE, leaving terms that explicitly depend on the magnetization. These disorder effects have also been incorporated into the semiclassical equations (Burgos Atencia et al., 2022). The case of magnetic impurities is qualitatively different, and relatively less studied (Nunner et al., 2008).

In the final analysis one needs to account for spin-orbit coupling both in the band structure and in the scattering potential, and for the interplay of the band structure spin-orbit coupling with scalar and spin-dependent disorder (Onoda et al., 2006; Borunda et al., 2007; Kovalev et al., 2009). In multi-band systems, where the spin precesses, this precession reduces the contributions of the extrinsic terms, and in certain cases causes them to vanish, as in a 2D electron gas. Asymmetric scattering of up and down spins takes place, but after scattering the spins precess and are randomized before reaching the boundary, and as they are randomized the resulting contributions to the AHE disappear. In single-band systems such as topological insulators the contributions due to extrinsic spin-orbit scattering are expected to be much smaller than the surviving terms from the band structure and scalar scattering discussed above.

To complete our discussion of scattering effects that are formally of zeroth order in the disorder strength we need to consider coherent backscattering. This refers to interference between the time-reversed incident and back-scattered paths in a scattering event. It is contained in the Cooperon, the sum of maximally crossed diagrams, which classically represents the probability that a particle will return to its starting position after scattering. The time over which the electron wave function retains its phase is determined by dynamic perturbations such as electron-electron, electron-phonon and electron-magnon scattering. In the absence of spin-orbit coupling coherent backscattering reduces the conductivity leading to weak localization. Spin-orbit coupling in the impurity potential or in the band structure leads to weak anti-localization and an increase in the conductivity. A magnetic field destroys phase coherence due to the difference in the Aharonov-Bohm phases of the two paths and with it coherent backscattering. At weak

magnetic fields coherent backscattering is present in the ordinary Hall effect but does not affect the Hall coefficient. Magnetic impurities reduce coherent backscattering but do not eliminate it.

In two dimensions coherent backscattering leads to a logarithmic dependence of the conductivity on the transport time τ , and a corresponding logarithmic temperature-dependence. It is predicted to affect the anomalous Hall conductivity. Theory concentrated on the role of extrinsic spin-orbit scattering, identifying a logarithmic τ - and temperature-dependence in the AHE (Dugaev et al., 2002; Wölfle and Muttalib, 2006). Being zeroth order in τ this is of the same order of magnitude to topological effects and their disorder corrections. Experiments on ferromagnetic thin films to date have reported a logarithmic temperature dependence of the AHE, believed to be due to weak localisation. The complex case of coherent backscattering in topological insulators, with strong band structure spin-orbit coupling, has not been studied theoretically or experimentally.

Anomalous Hall effects in topological materials

The revolutionary role of topological materials became apparent when it was demonstrated that the anomalous Hall effect in topological insulators can be quantized (Yu et al., 2010), with the conductivity

$$\sigma_{xy}^{QAHE} = \frac{e^2}{h}. \quad (17)$$

Four years after its theoretical prediction the quantized anomalous Hall was observed in a Bi_2Se_3 thin film (Chang et al., 2013), followed by studies reporting precise quantization (Bestwick et al., 2015). Results from the latter experiment are shown in Fig. 9. Although the possibility of quantization had been discussed in two-dimensional ferromagnets (Onoda and Nagaosa, 2003a, 2003b), the prediction and observation of this effect in topological insulators marks a cornerstone of modern physics (Liu et al., 2016).

The effect can be explained using either a surface state picture or an edge state picture. In the former we resort to the topological mechanism discussed above. The sample is a thin TI film doped with magnetic impurities in which ferromagnetic order occurs through the van Vleck mechanism. The chemical potential lies in the magnetization-induced gap between the surface valence and conduction bands, hence the material is in the insulating state. We envisage one surface, for example the top, of such a topological insulator and integrate the Berry curvature over the entire valence band, which yields a quantized conductivity $\sigma_{xy}^{2D} = \frac{e^2}{2h}$ due to the Berry curvature monopole at the top of the valence band. The bottom surface makes the same contribution once we take into account the fact that the normal to it points in the opposite direction. Altogether thus we have $\sigma_{xy}^{QAHE} = \frac{e^2}{h}$. Mathematically, the Hamiltonian describing the states on the top and bottom surfaces can be broken up into two blocks, and a sufficiently large magnetization gives rise to a difference in Chern number of one between the two blocks. Alternatively one can demonstrate that, when the Fermi energy is in the gap between the surface valence and conduction bands, a topological insulator possesses spin polarized edge states, which travel ballistically and may be described using a Landauer-Buttiker picture. The presence of a single channel results in a quantized conductivity of $\frac{e^2}{h}$. Remarkably, the quantized result holds even in the presence of disorder and electron-electron interactions.

A recurring problem in topological insulators is the presence of unintentional bulk carriers, which may place the Fermi energy in the bulk conduction band. Interestingly, the same physics leading to the quantized anomalous Hall effect causes a topological insulator thin film weakly coupled to a ferromagnet to exhibit strong magneto-optical Kerr and Faraday effects, which are less likely to be affected by unintentional bulk carriers (Tse and MacDonald, 2010). At low frequencies the Faraday rotation angle has a universal value, which is determined by the vacuum fine structure constant, when the Fermi energy lies in the Dirac gap for both

Fig. 9 Quantized anomalous Hall effect in $(\text{Cr}_{0.12}\text{Bi}_{0.26}\text{Sb}_{0.62})_2\text{Te}_3$. From Bestwick AJ et al. (2015) Precise quantization of the anomalous Hall effect near zero magnetic field. *Physical Review Letters* **114**: 187201.

surfaces. The Kerr rotation angle in this regime is universal and equal to $\pi/2$, hence the nomenclature of a giant Kerr rotation. The giant Kerr effect explicitly involves both surfaces and reflects the interplay between the chiral nature of the topological surface states and interference between waves reflected off the top surface and waves scattered off the bottom surface. The surface Hall response creates a splitting between the reflected left-handed and right-handed circularly polarized fields along the transverse direction. The left-handed and right-handed circularly polarized fields each acquire a phase of approximately $\pi/2$ in opposite directions, leading to a $\pi/2$ Kerr rotation.

If the topological insulator surface states are metallic, that is if the conduction band is occupied, the physical situation is quite different due to the presence of Berry curvature monopoles of opposite polarities at the top of the valence band and the bottom of the conduction band. When the chemical potential is in the gap one expects one TI surface to contribute $\sigma_{xy}^{TI} = \frac{e^2}{h}$ to the anomalous Hall conductivity. As soon as the chemical potential passes the bottom of the conduction band this topological contribution is cancelled by the Berry curvature monopole in the conduction band (Nomura and Nagaosa, 2011). What remains is the Fermi surface contribution, which depends on the magnetization and on the disorder profile (Sinitsyn et al., 2007). This dependence is rather subtle, and capturing it correctly requires including crossed diagrams, which are of higher order in the disorder strength (Ado et al., 2015; Ado et al., 2017). Interestingly, the anomalous Hall conductivity in doped topological insulators has been observed to have different signs under nominally identical conditions. Such a sign change could be explained by the correlation between the charge and spin part of the potential characterizing magnetic impurities (Keseser et al., 2019).

The anomalous Hall effect in time-reversal breaking Weyl semimetals can be understood straightforwardly. We recall that the anomalous Hall conductivity of 2D massive Dirac fermions is $\sigma_{xy}^{2D} = \frac{e^2}{2h}$ when the chemical potential lies in the gap. In the 3D case of Weyl semimetals the anomalous Hall conductivity is nonzero only in the region $-k_0 < k_z < k_0$, hence the relevant part of the 3D phase space is an infinite collection of 2D planes spanning this interval, each plane contributing the 2D conductivity quantum. This is equivalent to integrating the 2D conductivity over the interval $-k_0 < k_z < k_0$, yielding (Burkov, 2014)

$$\sigma_{xy}^{3D} = \frac{e^2}{2\pi^2}. \quad (18)$$

The anomalous Hall effect in Weyl semimetals is also quantized when the chemical potential lies near the bottom of the conduction band. Due to the presence of the node wave vector k_0 the quantised value is extremely large, and overwhelms any additional contributions that may arise from a finite electron density in the conduction band. Remarkably, corrections due to scalar disorder vanish altogether (Sekine et al., 2017).

Topological materials have been instrumental in revealing a series of close relatives of the AHE. To begin with transition metal dichalcogenides have two degenerate valleys, which are related by time reversal, so that the masses in the two valleys have opposite signs. Unlike graphene they typically have sizable spin-orbit interactions. Given that the spin is essentially locked to the valleys it is not clear that the two can be manipulated independently, yet accessing the elusive valley degree of freedom is fascinating from a fundamental standpoint. The analogue of the anomalous Hall effect in doped transition metal dichalcogenide monolayers is the valley Hall effect, which has been detected in MoS₂ (Mak et al., 2014). Physically it corresponds to an anomalous Hall effect with different signs for different valleys. There is no net charge current, because the anomalous Hall currents from the two valleys cancel each other out, but electrons from different valleys flow to different sides of the sample generating a valley polarization, which can be detected using circularly polarized light. The valley Hall effect generates a non-local resistance, which has a non-trivial dependence on the longitudinal resistivity.

The past decade has witnessed a surge in interest in Hall effects in two-dimensional systems in response to an in-plane magnetic field. In the classical theory a Hall effect is not expected when the magnetic field is in the plane of the sample: the ordinary Hall effect occurs because the Lorentz force causes electrons to move in cyclotron orbits perpendicular to it. Nevertheless an in-plane magnetic field can induce a planar Hall effect in topological materials, since protection from backscattering is removed for spins perpendicular to the magnetic field, but is retained for spins parallel to it (Taskin et al., 2017). The planar Hall effect has contributions from the Berry phase and orbital magnetic moment, and an anomalous planar Hall effect has likewise been predicted, driven by topological mechanisms (Zyuzin, 2020; Cullen et al., 2021; Battilomo et al., 2021; Tan et al., 2021). These investigations reveal that topological effects can influence the response to a magnetic field, blurring the boundary between ordinary and anomalous Hall effects.

Non-linear electrical effects are enabled by a lack of inversion symmetry, the application of a magnetic field, or the presence of a valley polarization. The quantity of interest in the second-order response is the next term in perturbation theory beyond the linear response to an electric field. The relevant signal can be detected by scanning higher harmonics of the applied frequency. The second-order response is not constrained by Onsager relations (Tokura and Nagaosa, 2018), thus non-linear Hall effects are allowed in time-reversal symmetric systems (Sodemann and Fu, 2015), and have been found to be particularly strong in transition metal dichalcogenides. Two papers have reported a non-linear anomalous Hall effect in bilayer/few-layer WTe₂ (Ma et al., 2019; Kang et al., 2019). In the former the non-linear anomalous Hall effect results in a much larger transverse than longitudinal voltage. The effect is generally extrinsic in time-reversal invariant systems, but can be intrinsic if time-reversal symmetry is broken. The static non-linear Hall conductivity contains an intrinsic contribution proportional to the Berry curvature dipole in reciprocal space, that is, the term $k\vec{\Omega}_n$, where we recall $\vec{\Omega}_n$ is the Berry curvature. The non-linear anomalous Hall effect is a new area of research, where significant developments are likely in the coming years.

Conclusion

The anomalous Hall effect has become a mainstay of modern condensed matter physics. Indispensable for its occurrence are ferromagnetism and spin-orbit coupling. Magnetic interactions contribute to the AHE either through the magnetization or through spin chirality, while spin-orbit coupling gives rise to a momentum-dependent effective magnetic field in the band structure, as well as to spin dependent scattering. The combination of an effective magnetic field and a magnetization is responsible for Berry curvature monopoles, and these generate a strong intrinsic topological contribution to the AHE, associated with the Fermi sea of electrons. In addition to this one may distinguish several extrinsic contributions due to scattering, associated with the Fermi surface, and stemming either from the spin dependence of the scattering potential, or from scalar scattering combined with the effective spin-orbit field in the band structure. Systems where both intrinsic and extrinsic effects are strong are complex, with various terms occasionally vanishing altogether: intrinsic processes may be cancelled out by scattering terms independent of the disorder concentration, while extrinsic effects are reduced by spin precession and in extreme cases vanish.

Many unanswered questions remain, and elucidating these will no doubt preoccupy researchers in the coming years, if not decades. Determining and understanding the temperature dependence of the AHE in all classes of materials in which it is observed, including the effect of magnetic excitations, is a major long term challenge for experiment as well as theory. At the fundamental level, the role of disorder in the AHE remains incompletely understood, in particular in dirty materials and in the hopping regime, while the role of localization effects has not been settled. In inhomogeneous ferromagnets disentangling the topological and anomalous Hall effects has emerged as a significant experimental hurdle. Designing devices that can harness the quantized AHE is a challenge for technological applications.

It is natural to expect relatives of the AHE to emerge in anti-ferromagnets, in particular topological anti-ferromagnets, and potentially in the non-linear regime. In this context we note that the same fundamental questions must be answered for the non-linear AHE—determining the relative sizes of intrinsic and disorder contributions, and of the Fermi surface and Fermi sea contributions. Moreover, the non-linear response is intensively studied at optical frequencies, where non-linear anomalous Hall effects and related phenomena exist both in the AC second-harmonic response and in the DC photo-current response, for example as part of rectification, shift and injection currents. Considerable growth is expected in this area, especially given the potential for applications in solar cells and opto-electronic devices.

Research on the anomalous Hall effect shows no sign of abating. One and a half centuries after its discovery we are not achieving closure but entering uncharted territory.

Abstract

This chapter presents the electronic properties of monolayer and bilayer graphene. It begins with an overview of graphene including its history, fabrication methods, properties, and current and potential applications. We then detail the tight-binding model in order to describe the emergence of the Dirac equation near the Fermi level in monolayer graphene and its consequences including massless charge carriers with a linear electronic dispersion, pseudospin and chirality, Berry phase π , Klein tunneling, and an unusual sequence of plateaus in the integer quantum Hall effect. We explain how this is generalized in Bernal-stacked bilayer graphene as characterized by a novel Hamiltonian describing massive chiral charge carriers and in AA-stacked bilayer graphene which displays two shifted copies of the monolayer bands at low energy.

Key points

- An overview of graphene including its history, fabrication methods, properties, and current and potential applications.
- The tight-binding model of electrons in monolayer and bilayer graphene.
- The emergence of the Dirac equation near the Fermi level in monolayer graphene.
- Consequences including massless charge carriers with a linear electronic dispersion, pseudospin and chirality, Berry phase π , Klein tunneling, and an unusual sequence of plateaus in the integer quantum Hall effect.

- Bernal-stacked bilayer graphene as characterized by a novel Hamiltonian describing massive chiral charge carriers.
- AA-stacked bilayer graphene which displays two copies of the monolayer bands at low energy.

Introduction

Graphene

Graphene is a two-dimensional material consisting of a single layer of carbon atoms arranged on a honeycomb lattice (Castro Neto et al., 2009). It was isolated by Andre Geim, Konstantin Novoselov and colleagues at the University of Manchester in 2004 (Novoselov et al., 2004), and the Nobel Prize in Physics 2010 was awarded to Geim and Novoselov 'for groundbreaking experiments regarding the two-dimensional material graphene'. A closely-related material is graphite (Dresselhaus and Dresselhaus, 2002) which is a three-dimensional stack of parallel, weakly-coupled layers of graphene. The phrase 'graphene' usually refers to a single layer, but is sometimes used more generally to refer to a quasi-two-dimensional very thin film of graphite, as in 'few-layer graphene' or 'multilayer graphene'; the phrase 'monolayer graphene' can be used specifically for a single layer to avoid ambiguity.

History

Prior to the 2004 isolation of graphene by Geim, Novoselov and colleagues (Novoselov et al., 2004), very thin films of graphite had been fabricated by various methods including reduction of graphene oxide, epitaxial growth, and mechanical cleavage (Geim, 2012). The 2004 paper (Novoselov et al., 2004) was a major step forward in the preparation of atomically-thin layers, but it also unearthed two amazing properties of graphene (Geim, 2012): the ambipolar electric field effect in which an applied gate voltage can tune the electronic density and related electronic properties, and remarkably high electrical mobility $\sim 10,000 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ at room temperature. Independent papers published in 2005 by Geim, Novoselov and colleagues (Novoselov et al., 2005), and Philip Kim and colleagues (Zhang et al., 2005) observed the integer quantum Hall effect with an unusual sequencing of quantized plateaus which confirmed predictions based on a low-energy theory of Dirac-like fermions (with linear dispersion) instead of the usual Schrödinger picture (with quadratic dispersion).

Theoretically, graphene has been studied for many years as a building block of graphite (DiVincenzo and Mele, 1984; Dresselhaus and Dresselhaus, 2002; McClure, 1956; Slonczewski and Weiss, 1958; Wallace, 1947), buckyballs (González et al., 1992) and carbon nanotubes (Ajiki and Ando, 1993; Ando et al., 1998; Kane and Mele, 1997; McEuen et al., 1999; Saito et al., 1998). Remarkably, this includes a description of the electronic band structure by Wallace in 1947 (Wallace, 1947) and the energy spectrum in a quantizing magnetic field (Landau level spectrum) by McClure in 1956 (McClure, 1956). In the 1980s, it was realised that the effective low-energy theory is that of Dirac fermions (DiVincenzo and Mele, 1984; Semenoff, 1984). Graphene also played a role in the understanding of topological insulators: the Haldane model (Haldane, 1988) and the Kane-Mele model (Kane and Mele, 2005a,b) are based on graphene and exemplify Chern insulators and spin-Hall insulators, respectively (Cayssol and Fuchs, 2021).

Fabrication

The fabrication of graphene by Geim, Novoselov and colleagues (Novoselov et al., 2004) was by mechanical exfoliation, informally known as the 'Scotch tape' or 'sticky tape' method. This generally yields high quality samples, but is labor intensive and low yield. It involves manually cleaving a piece of graphite along the in-plane direction, possibly using sticky tape. The resulting collection of smaller samples is placed on a substrate (such as silicon) and identified using optical microscopy (Orlita and Potemski, 2010). A possible way to accelerate this process is to employ ultrasonic exfoliation.

There are many other methods to fabricate graphene (Ferrari et al., 2015; Zhu et al., 2010). In chemical reduction of graphene oxide (Pei and Cheng, 2012), graphite oxide is prepared by oxidation of graphite and is subsequently broken up using ultrasonic exfoliation in water to create graphene oxide; this can then be chemically reduced to produce graphene. Graphene can be grown by chemical vapor deposition (CVD) growth on metallic substrates (Bae et al., 2010; Kim et al., 2009; Li et al., 2009a), allowing for large area samples, but often containing grain boundaries. Graphene can also be grown epitaxially on SiC whereby, at high temperature, silicon sublimates leaving a carbon-rich surface which forms graphene (de Heer et al., 2011).

Properties

Graphene is extremely strong with an intrinsic strength $\sim 130 \text{ GPa}$ (Lee et al., 2008a) and it is very rigid when tension is applied in the in-plane direction with Young's modulus $\sim 1 \text{ TPa}$ (Lee et al., 2008a). However, it is flexible and can bend in response to an out-of-plane force, with bending stiffness $\sim 1 \text{ eV}$ (Han et al., 2020). It is chemically stable at room temperature when exposed to air, but graphene begins to react with oxygen gas above 200°C (Liu et al., 2008; Yamada et al., 2014).

The Dirac-like low energy electronic dispersion yields a linear electronic dispersion over an energy scale of the order of 1 eV with zero band gap between the conduction and valence bands. Graphene is almost transparent, absorbing about 2.3% of incoming light across the whole visible spectrum, and this fraction is equal to $\pi\alpha$ where α is the fine structure constant (Nair et al., 2008; Orlita and Potemski, 2010). Graphene is an excellent electrical conductor with room temperature mobility in excess of $100,000 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$.

reported for high quality samples (typically suspended above a substrate (Bolotin et al., 2008; Du et al., 2008) or encapsulated in boron nitride (Mayorov et al., 2011)). This corresponds to ballistic transport over a distance more than $1\text{ }\mu\text{m}$ at room temperature (Mayorov et al., 2011). It is also an excellent thermal conductor, with thermal conductivity up to $\sim 5000\text{ W m}^{-1}\text{ K}^{-1}$ at room temperature (Balandin et al., 2008).

Applications

Graphene is used as conductive ink for printed electronics, as heat sinks in electronic devices including mobile phones and computer components, and graphene composites are employed in advanced sportswear and equipment. In addition, graphene is being studied for its possible use in a wide range of other applications (Ferrari et al., 2015; Novoselov et al., 2012).

In electronics, there is potential as a flexible and transparent conductive coating for touch screen displays, electronic paper, and organic light-emitting diodes (Avouris, 2010; Ferrari et al., 2015; Novoselov et al., 2012; Zhu et al., 2010). There is research into the use of graphene-based transistors, although the absence of an electronic band gap tends to compromise the on/off ratio, limiting the use of graphene in logic transistors (Avouris, 2010). However graphene may still be useful in high-frequency applications (Avouris, 2010; Ferrari et al., 2015; Gayduchenko et al., 2021). There is also interest in applications to thermal management (Fu et al., 2020) and interconnects in integrated circuits (Ferrari et al., 2015). Owing to weak spin-orbit coupling in graphene, it may have applications in spintronic devices as a non-magnetic channel with a long spin-relaxation time (Ferrari et al., 2015; Pesin and MacDonald, 2012).

The gapless, linear dispersion of electrons results in almost constant absorption of light over a wide range from infrared to ultraviolet. Coupled with the high electronic mobility, this suggests use in photonic devices including photodetectors, optical modulators, and saturable absorbers for lasers (Avouris, 2010; Ferrari et al., 2015; Peng and Yan, 2021; Yamashita, 2019). Owing to its two-dimensional nature, strength, and ability to be functionalized by various chemical species, the use of graphene is being explored in a wide range of sensors (e.g., for gas, strain, electromagnetic waves, biosensors) (Ferrari et al., 2015; Schedin et al., 2007). As well as biosensors, there are potential bioapplications in areas such as drug delivery and tissue engineering (Ferrari et al., 2015; Wang et al., 2011). It also has possible application in energy generation and storage including solar cells, supercapacitors, batteries and hydrogen storage (Bonaccorso et al., 2015; Ferrari et al., 2015; Zhu et al., 2010). Graphene promises a new resistance standard (Ferrari et al., 2015; Janssen et al., 2013) based on the large gap between energy levels in an external magnetic field (Landau levels), as manifested in the integer quantum Hall effect.

Electrical properties of monolayer graphene

Crystal structure

Carbon has atomic number 6. Two of its electrons are core electrons in the first shell, the other four are valence electrons in the second shell. In crystals, the latter occupy $2s$, $2p_x$, $2p_y$ and $2p_z$ orbitals, and the mixing of the $2s$ orbital with $n = 1, 2$ or 3 of the p orbitals gives rise to sp^n hybridization. This enables the existence of different allotropes of carbon. For example, diamond is an example of sp^3 hybridization, whereas graphite and graphene have sp^2 hybridization (Saito et al., 1998).

Typically, graphene is considered to lie in the x - y plane, with mixing of the $2s$ orbital with the $2p_x$ and $2p_y$ orbitals. Such mixing results in very strong σ bonds between each carbon atom and its three neighbors, creating a honeycomb lattice as shown in Fig. 1. The corresponding σ electronic energy bands are gapped, and lie a few electron volts away from the Fermi level (Saito et al., 1998). However, the remaining $2p_z$ orbital on each atom forms relatively weak π bonds with neighboring atoms, resulting in π bands at the Fermi level. The resulting electronic states are extended over the system, causing metallic behavior.

Fig. 1 Schematic of the honeycomb lattice of graphene with black circles indicating carbon atoms and solid straight lines representing covalent σ bonds between neighboring atoms. The shaded rhombus represents a unit cell containing two atomic positions, labeled A and B, and a is the lattice constant.

Fig. 2 (A) Schematic of the reciprocal lattice (crosses) and the first Brillouin zone (hexagon) showing symmetry points Γ at the origin, and K_+ and K_- at the corners of the first Brillouin zone. (B) Electronic band structure according to Eq. (3) with $\gamma_0 = 3$ eV plotted along the line $k_y = 0$. Vertical dashed lines show the positions of the symmetry points Γ , K_+ and K_- .

The honeycomb lattice, Fig. 1, is not a Bravais lattice because there are two nonequivalent atomic positions A and B, i.e., the honeycomb lattice consists of a hexagonal Bravais lattice with a basis of two atoms per unit cell. With lattice constant $a = 2.46$ Å, the interatomic separation is $a/\sqrt{3} = 1.42$ Å. If one would consider only A atoms, they would lie on a hexagonal Bravais lattice, likewise the B atoms. Hence one speaks of A and B sublattices.

Band structure and tight-binding model

The honeycomb lattice consists of a hexagonal Bravais lattice with a basis of two atoms per unit cell, denoted A and B, Fig. 1. Electronic energy bands at the Fermi level are π bands arising from the mixing of one $2p_z$ electronic orbital per atom. With one $2p_z$ orbital per atom and two atoms per unit cell, there are two orbitals per cell which yield two energy bands. Assuming translational invariance within the graphene plane, it is possible to derive a Bloch Hamiltonian $H(\mathbf{k})$ as a two-component matrix in the basis of Bloch orbitals on A and B sites, where $\mathbf{k} = (k_x, k_y)$ is the wave vector (Saito et al., 1998). The reciprocal lattice is a hexagonal Bravais lattice, and the first Brillouin zone is a hexagon, as shown in Fig. 2A.

Including only coupling between nearest-neighbor A and B sites, and assuming atomic orbitals on adjacent atoms are orthogonal, the tight-binding Bloch Hamiltonian is

$$H(\mathbf{k}) = \begin{pmatrix} 0 & -\gamma_0 f(\mathbf{k}) \\ -\gamma_0 f^*(\mathbf{k}) & 0 \end{pmatrix}, \quad (1)$$

$$f(\mathbf{k}) = e^{ik_y a/\sqrt{3}} + 2e^{-ik_y a/(2\sqrt{3})} \cos(k_x a/2), \quad (2)$$

where a is the lattice constant and $\gamma_0 \approx 3$ eV (Dresselhaus and Dresselhaus, 2002; Saito et al., 1998) is the nearest-neighbor hopping parameter. The two energy bands are given by

$$E_{\pm}(\mathbf{k}) = \pm \gamma_0 |f(\mathbf{k})|, \quad (3)$$

and are plotted in Fig. 2B along the line $k_y = 0$.

Given twofold spin degeneracy, graphene is at half filling at charge neutrality (i.e., when the system isn't doped or exposed to external gating). In this case the Fermi level will lie at $E = 0$. Fig. 2 indicates notable symmetry points in the first Brillouin zone, namely Γ at the origin, and K_+ and K_- at the corners of the first Brillouin zone. Note that we only discuss two distinct corners (K_+ and K_-) because the other corners are equivalent (to either K_+ or K_-) via a translation by a reciprocal lattice vector. From the band structure, Fig. 2B, it can be seen that there is no band gap between the two bands, and that there is band degeneracy at the two K points (K_+ and K_-) at $E = 0$. Moreover, the electronic dispersion is approximately linear near these points over a large energy scale ~ 1 eV. Note that the K points are also referred to as the two valleys of graphene. The degeneracy at the valley centers arises because $f(\mathbf{k}) = 0$ there. It means that the A and B sublattices have no coupling between them, but, being identical hexagonal Bravais lattices consisting of carbon atoms, they support two degenerate electronic states.

Dirac effective-mass model, pseudospin and chirality

The two valley centers, K_+ and K_- , are located at wave vectors $\mathbf{k}_\xi = \xi(4\pi/(3a), 0)$ where the valley index $\xi = \pm 1$ is used to distinguish them. Since $f(\mathbf{k}_\xi) = 0$, it is possible to derive a continuum effective-mass model by expanding the function $f(\mathbf{k})$, Eq. (2), near the valley centers $\mathbf{k}_\xi$ using $\mathbf{k} = \mathbf{k}_\xi + \mathbf{q}$ where $|\mathbf{q}|a \ll 1$. To linear order in $|\mathbf{q}|a$, this is $\gamma_0 f(\mathbf{k}_\xi + \mathbf{q}) = -\hbar v(\xi q_x - iq_y)$ where $v = \sqrt{3}a\gamma_0/(2\hbar) \approx 10^6 \text{ m s}^{-1}$ has physical dimensions of velocity. Then, the Hamiltonian $H(\mathbf{k})$, Eq. (1), may be approximated as

$$H_\xi(\mathbf{q}) = \begin{pmatrix} 0 & \hbar v(\xi q_x - iq_y) \\ \hbar v(\xi q_x + iq_y) & 0 \end{pmatrix}. \quad (4)$$

The subscript ξ is used to stress that this is valid near each valley K_ξ .

The effective mass model $H_\xi(\mathbf{q})$ describes the linear dispersion of the gapless energy bands near the valleys and the Fermi level ($E = 0$),

$$E_\pm(\mathbf{q}) = \pm \hbar v |\mathbf{q}|. \quad (5)$$

Corresponding eigenstates can be conveniently written as

$$\psi_\pm = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ \pm \xi e^{-i\xi\phi} \end{pmatrix}, \quad (6)$$

where ϕ is the polar angle of the wave vector, $q_x = |\mathbf{q}| \cos \phi$, $q_y = |\mathbf{q}| \sin \phi$. Taking into account twofold spin degeneracy and twofold valley degeneracy, the isotropic dispersion Eq. (5) yields a density of states per unit energy per unit area given by

$$g(E) = \frac{2}{\pi} \frac{|E|}{\hbar^2 v^2}, \quad (7)$$

and Fermi velocity $v_F = v$.

Effective mass models often have the form of a Schrödinger equation yielding quadratic energy $E = \hbar^2 k^2/(2m_*)$ with effective mass m_* . Here, instead, the dispersion is linear, reminiscent of relativistic dynamics, with velocity $v \approx 10^6 \text{ m s}^{-1}$ significantly less than the speed of light in vacuum. Although Eq. (4) is written near a single valley, if one explicitly included both valleys the effective mass model would have four components and it would be the massless Dirac equation in two spatial dimensions. The dispersion Eq. (5) describes a Dirac cone at each valley, and the valley center is often referred to as a Dirac point. Note that the two components of $H_\xi(\mathbf{q})$, Eq. (4), are not electron spin (we assume twofold spin degeneracy), but the A, B sublattice degree of freedom, which is known as pseudospin.

The pseudospin may be represented using Pauli spin matrices in the A, B sublattice space so that

$$H_\xi(\mathbf{q}) = \hbar v (\xi q_x \sigma_x + q_y \sigma_y). \quad (8)$$

For a vector of Pauli spin matrices $\boldsymbol{\sigma} = (\sigma_x, \sigma_y, \sigma_z)$, its expectation value with respect to the eigenstates Eq. (6) is $\langle \psi_\pm | \boldsymbol{\sigma} | \psi_\pm \rangle = \pm \hat{\mathbf{n}}_1$ where the unit vector $\hat{\mathbf{n}}_1$ is

$$\hat{\mathbf{n}}_1 = (\xi \cos \phi, \sin \phi, 0). \quad (9)$$

Thus the Hamiltonian may be further written as

$$H_\xi(\mathbf{q}) = \hbar v |\mathbf{q}| \boldsymbol{\sigma} \cdot \hat{\mathbf{n}}_1, \quad (10)$$

which emphasizes that electrons in graphene are chiral. Energy eigenstates $\psi_\pm$ with $E_\pm(\mathbf{q}) = \pm \hbar v |\mathbf{q}|$ also have eigenvalues $\boldsymbol{\sigma} \cdot \hat{\mathbf{n}}_1 = \pm 1$ for measurement of pseudospin along the direction $\hat{\mathbf{n}}_1$. The pseudospin direction is linked to that of the electronic wave vector (e.g., at valley $\xi = 1$, they are parallel for the conduction band and antiparallel for the valence band).

Symmetries

In the absence of external perturbations, graphene satisfies space and time inversion symmetries. Both of these involve inversion of the wave vector $\mathbf{k}$ so that, when applied to electronic states in the vicinity of a valley as described by $H_\xi(\mathbf{q})$, the valley index must be inverted $\xi \rightarrow -\xi$:

$$\text{space inversion : } \sigma_x H_\xi(\mathbf{q}) \sigma_x = H_{-\xi}(-\mathbf{q}), \quad (11)$$

$$\text{time inversion : } H_\xi^*(\mathbf{q}) = H_{-\xi}(-\mathbf{q}). \quad (12)$$

Note that some authors discuss an additional fictitious time inversion symmetry which acts at one valley as $\sigma_y H_\xi^*(\mathbf{q}) \sigma_y = H_\xi(-\mathbf{q})$ without inverting the valley index.

Chiral, or sublattice, symmetry is described by the Pauli matrix σ_z in the A, B sublattice space (Cayssol and Fuchs, 2021) and acts as

$$\text{chiral : } \sigma_z H_\xi(\mathbf{q}) \sigma_z = -H_\xi(\mathbf{q}). \quad (13)$$

Chiral symmetry ensures electron-hole symmetry of the electronic spectrum, as shown in Fig. 2B. Chiral symmetry may be combined with time-inversion symmetry to give charge conjugation symmetry $\sigma_z H_\xi^*(\mathbf{q}) \sigma_z = -H_{-\xi}(-\mathbf{q})$. Note that the preservation of chiral symmetry (and charge conjugation) is only approximately correct at low energy, due to approximations made in deriving the tight-binding model Eq. (1). For example, introducing non-orthogonality of adjacent $2p_z$ orbitals will break electron-hole symmetry of the band structure (Saito et al., 1998).

Berry phase π

Graphene satisfies space and time inversion symmetries, so Berry curvature is zero everywhere (Cayssol and Fuchs, 2021; Xiao et al., 2010). Nevertheless, it is possible to accumulate non-zero Berry phase along a closed trajectory in reciprocal space which encloses a valley center. Consider, for example, states $\psi_\pm$ near a valley center as described by Eq. (6), and a closed circular trajectory C at constant energy and a constant radial distance $|\mathbf{q}|$ from the valley center. The Berry connection $\mathbf{A}_\pm(\mathbf{q})$ is defined (Berry, 1984) as

$$\mathbf{A}_\pm(\mathbf{q}) = i \langle \psi_\pm | \nabla_{\mathbf{q}} | \psi_\pm \rangle, \quad (14)$$

which may be evaluated as $\mathbf{A}_\pm(\mathbf{q}) = -\xi \hat{\mathbf{e}}_\phi / (2|\mathbf{q}|)$ where $\hat{\mathbf{e}}_\phi$ is the unit vector of polar angle ϕ . The Berry phase is

$$\gamma_\pm = \oint_C \mathbf{A}_\pm(\mathbf{q}) \cdot d\mathbf{q} = -\xi\pi. \quad (15)$$

This is somewhat analogous to a winding number because the accumulated Berry phase is nonzero only when the path encloses the valley center. Note that the Berry connection is not gauge invariant, and that the Berry phase is only defined modulo 2π . Whatever gauge is chosen for the eigenstates $\psi_\pm$, they should be single-valued around the trajectory C for the calculation of Berry phase to be valid.

It is possible to imagine breaking inversion symmetry in graphene by introducing asymmetry between the A and B onsite energies, modifying the effective mass model (Semenoff, 1984) as

$$H_\xi(\mathbf{q}) = \hbar v \left(\xi q_x \sigma_x + q_y \sigma_y \right) + \Delta \sigma_z, \quad (16)$$

where Δ is a real parameter characterizing the asymmetry as $E_A - E_B = 2\Delta$. It opens a gap in the energy spectrum, $E_\pm(\mathbf{k}) = \pm \sqrt{\Delta^2 + \hbar^2 v^2 |\mathbf{q}|^2}$, and leads to non-zero Berry curvature (Xiao et al., 2007, 2010),

$$\Omega_\pm(\mathbf{q}) = \mp \frac{\xi \Delta \hbar^2 v^2}{2(\hbar^2 v^2 |\mathbf{q}|^2 + \Delta^2)^{3/2}}. \quad (17)$$

The Berry curvature is strongly peaked near the valley center, but with opposite signs at the two valleys. Hence, the contributions of the valleys cancel to give zero Chern number for the filled valence bands (as expected because time-inversion symmetry is preserved). Although the Chern number is zero, the Dirac effective mass model of graphene is an important example of a two-band model, and it played a role in the understanding of topological insulators. Particularly, the Haldane model (Haldane, 1988) and the Kane-Mele model (Kane and Mele, 2005a,b) are based on graphene and exemplify Chern insulators and spin-Hall insulators, respectively (Cayssol and Fuchs, 2021).

Trigonal warping and other tight-binding parameters

The Dirac-like effective mass model Eq. (4) is linear in the wavevector $\mathbf{q}$ measured from the valley center, and this is generally a good approximation when $|\mathbf{q}|$ is small, i.e., $|\mathbf{q}|a \ll 1$. It gives the isotropic electronic dispersion $E_\pm(\mathbf{q}) = \pm \hbar v |\mathbf{q}|$, Eq. 5. Corrections emerge at larger $|\mathbf{q}|$ values, and they may be included by expanding $f(\mathbf{k}_\xi + \mathbf{q})$ to higher powers in $|\mathbf{q}|$. For example, to quadratic order (Ando et al., 1998),

$$H_\xi(\mathbf{q}) = \begin{pmatrix} 0 & \hbar v (\xi q_x - i q_y) \\ \hbar v (\xi q_x + i q_y) & 0 \end{pmatrix} - \frac{\gamma_0 a^2}{8} \begin{pmatrix} 0 & (\xi q_x + i q_y)^2 \\ (\xi q_x - i q_y)^2 & 0 \end{pmatrix}. \quad (18)$$

The corresponding energy eigenvalues are

$$E_\pm(\mathbf{q}) = \pm \hbar v |\mathbf{q}| \sqrt{1 - \frac{\xi |\mathbf{q}| a \cos(3\phi)}{2\sqrt{3}} + \frac{|\mathbf{q}|^2 a^2}{48}}. \quad (19)$$

With the dependence on $\cos(3\phi)$ where ϕ is the polar angle of the wavevector, this describes a triangular-shaped distortion to the otherwise circular Fermi surface known as ‘trigonal warping’. It is illustrated in Fig. 3 for valley K_+ ; note that the orientation of trigonal warping is reversed at the other valley K_- . Even at a rather large energy (e.g., $E \approx 1.2$ eV in Fig. 3), the perturbation due to

Fig. 3 Trigonal warping in graphene at the K_+ valley showing a constant energy contour $E = 0.4\gamma_0 \approx 1.2$ eV. The solid line shows the influence of trigonal warping Eq. (19) as compared to its absence in the isotropic dispersion $E = \hbar v|\mathbf{q}|$ (dashed line).

trigonal warping is relatively slight. The Hamiltonian with trigonal warping Eq. (18) satisfies chiral symmetry Eq. (13), so electron-hole symmetry of the energy spectrum is maintained.

It is possible to consider tight-binding parameters in addition to the nearest-neighbor hopping γ_0 . One example is to take into account non-orthogonality of $2p_z$ orbitals on adjacent sites (Saito et al., 1998), another is to include next-nearest neighbor hopping (Johnson and Dresselhaus, 1973; Peres et al., 2006; Sasaki et al., 2006; Wallace, 1947). Both of these break chiral symmetry Eq. (13) and, thus, introduce electron-hole asymmetry in the band structure. However, they are both quadratic in $\mathbf{q}$ corrections to the Dirac-like effective mass model so are very small at low energy.

Ambipolar electric field effect

The carrier density n in graphene may be tuned using an external gate potential, and this allows the measurement of the density-dependence of many physical observables (Novoselov et al., 2004). Graphene has a gapless band structure with degeneracy at the valley centers, Fig. 2B. As measured from the valley center, for a partially-filled conduction band, the carrier density n is given by

$$n = \frac{q_F^2}{\pi} = \frac{E_F^2}{\pi \hbar^2 v^2}, \quad (20)$$

where q_F (E_F) is the magnitude of the Fermi wavevector (energy), and this expression includes fourfold band degeneracy (for spins and valleys). The density n may be tuned (Novoselov et al., 2004) using a gate parallel to the graphene of voltage V_g , separated at a distance d by a spacer with dielectric constant ϵ_g . Modeling the gate and graphene as two surfaces of a parallel plate capacitor, the carrier density is

$$n = \frac{\epsilon_0 \epsilon_g}{ed} V_g, \quad (21)$$

where we use SI units and denote electronic charge as $-e$ with $e > 0$.

Klein tunneling

Klein tunneling is a process in which chiral electrons in graphene display perfect transmission at normal incidence on a potential barrier (Ando et al., 1998; Beenakker, 2008; Castro Neto et al., 2009; Cheianov and Fal'ko, 2006; Katsnelson et al., 2006; McEuen et al., 1999). It is the result of a continuous, gapless energy spectrum between the conduction and valence bands, and of conservation of pseudospin as a particle travels between the states in those bands.

To demonstrate this effect, we consider a potential $V(x)$ with translational invariance in the transverse direction y , but with a step dependence in the longitudinal x direction (Katsnelson et al., 2006) such that $V(x) = 0$ for $x < 0$ and for $x > L$, and $V(x) = V_0$ for $0 < x < L$, as shown in Fig. 4. The low energy Hamiltonian Eq. (4) in real space is written as

$$H_\xi = \begin{pmatrix} V(x) & v(\xi p_x - i p_y) \\ v(\xi p_x + i p_y) & V(x) \end{pmatrix}, \quad (22)$$

Fig. 4 Klein tunneling in graphene. (A) Schematic of an incoming electron of energy E and longitudinal wavevector component k_x incident on a square potential barrier of height V_0 and length L . (B) Schematic of the relative positions of the graphene energy bands for the case $V_0 > E > 0$. A normally incident electron on the left with wavevector k_x in the conduction band transfers to a state in the valence band under the barrier with wavevector $-q_x$, which then transfers to an outgoing state on the right with wavevector k_x in the conduction band. (C) Transmission probability $T(\phi)$ as a function of incident angle ϕ for incoming electrons of energy $E = 70$ meV ($\lambda = 59$ nm), barrier length $L = 120$ nm and barrier heights $V_0 = 200$ meV (solid) and $V_0 = 300$ meV (dashed). (D) Transmission probability $T(\phi)$ for incoming electrons of energy $E = 70$ meV ($\lambda = 59$ nm), barrier length $L = 180$ nm and barrier heights $V_0 = 200$ meV (solid) and $V_0 = 300$ meV (dashed). Plots were made with velocity $v = 1.0 \times 10^6$ m s $^{-1}$.

where p_x, p_y are components of the momentum operator. For an incoming wave of unit flux from the left side, we determine solutions to the Hamiltonian on the left $x < 0$, ψ_L , in the center $0 < x < L$, ψ_C , and on the right $x > L$, ψ_R . Then, we use wave matching to determine the transmission probability, assuming planar interfaces at the boundaries $x = 0$ and $x = L$ such that the transverse component k_y of the wave vector is conserved. The states can be written as

$$\begin{aligned}\psi_L &= \left[\begin{pmatrix} 1 \\ s_C \xi e^{-i\xi\phi} \end{pmatrix} e^{ik_x x} + r \begin{pmatrix} 1 \\ -s_C \xi e^{-i\xi\phi} \end{pmatrix} e^{-ik_x x} \right] e^{ik_y y}, \\ \psi_C &= \left[C \begin{pmatrix} 1 \\ s_C \xi e^{i\xi\theta} \end{pmatrix} e^{iq_x x} + D \begin{pmatrix} 1 \\ -s_C \xi e^{-i\xi\theta} \end{pmatrix} e^{-iq_x x} \right] e^{ik_y y}, \\ \psi_R &= t \begin{pmatrix} 1 \\ s_C \xi e^{i\xi\phi} \end{pmatrix} e^{ik_x x + ik_y y},\end{aligned}$$

where r , t , C , and D are constants to be determined by the wave matching (r and t are reflection and transmission amplitudes, respectively). On the left and the right, the energy is $E = s\hbar v \sqrt{k_x^2 + k_y^2}$ where $s = \text{sign}(E)$, and ϕ is the polar angle, $\tan \phi = k_y/k_x$. In the center, $E = V_0 + s_C \hbar v \sqrt{q_x^2 + k_y^2}$ where $s_C = \text{sign}(E - V_0)$, and θ is the polar angle, $\tan \theta = k_y/q_x$.

As the Hamiltonian Eq. (22) is linear in momentum, it is sufficient to match the sublattice components of the states at $x = 0$ and at $x = L$, not their spatial derivatives. This process yields the reflection $R = |r|^2$ and transmission $T = |t|^2$ probabilities, where $R + T = 1$, as (Castro Neto et al., 2009; Katsnelson et al., 2006)

$$R = \frac{(\sin \phi - s_C \sin \theta)^2 \sin^2 q_x L}{\cos^2 \phi \cos^2 \theta \cos^2 q_x L + (s_C - \sin \phi \sin \theta)^2 \sin^2 q_x L},$$

$$T = \frac{\cos^2 \phi \cos^2 \theta}{\cos^2 \phi \cos^2 \theta \cos^2 q_x L + (s_C - \sin \phi \sin \theta)^2 \sin^2 q_x L}.$$

They are both independent of the valley index ξ . These expressions show that there are resonances at $q_x L = \pi N$, for integer N , when $R = 0$ and $T = 1$. In addition, there is also perfect transmission $R = 0$ and $T = 1$ at normal incidence $\phi = \theta = 0$. Plots of the transmission probability T as a function of the polar angle ϕ of incoming electrons are shown in Fig. 4C and D for different parameter values, illustrating the perfect transmission at normal incidence and the parameter-dependent resonances at other angles.

Perfect transmission at normal incidence $\phi = \theta = 0$ is illustrated in Fig. 4B. In this case, with $V_0 > E > 0$, $s = 1$, $s_C = -1$, $r = C = 0$ and $|t| = |D| = 1$: as the potential $V(x)$ is diagonal in the A/B sublattice space, it is unable to change the direction of pseudospin which must be conserved as a particle crosses the barrier. In this case, the pseudospin points in the direction of positive x and all the non-zero states have the form $\psi^T \sim (1 \ 1)$ in the A/B sublattice space.

Integer quantum Hall effect

Landau levels

In the presence of a perpendicular magnetic field, the energy spectrum consists of a series of discrete energy levels known as Landau levels. Off-diagonal elements of the Dirac effective-mass model, Eq. (4), act on magnetic oscillator states as raising or lowering operators (Castro Neto et al., 2009). With magnetic field $\mathbf{B} = (0, 0, -B)$ (in Cartesian coordinates) and the Landau gauge for vector potential $\mathbf{A} = (0, -Bx, 0)$, then, at the first valley,

$$H_+ = \frac{\sqrt{2}\hbar v}{\lambda_B} \begin{pmatrix} 0 & ia^\dagger \\ -ia & 0 \end{pmatrix}, \quad (23)$$

where $\lambda_B = \sqrt{\hbar/(eB)}$ is the magnetic length, and $a^\dagger, a$ are raising and lowering operators which act on magnetic operator states ϕ_ℓ as

$$a^\dagger \phi_\ell = \sqrt{\ell + 1} \phi_{\ell+1}, \quad (24)$$

$$a \phi_\ell = \sqrt{\ell} \phi_{\ell-1}, \quad (25)$$

where ℓ is an integer with $\ell \geq 0$ and $a\phi_0 = 0$. Two-component eigenstates $\psi_{\ell,\pm}$ for $\ell \geq 1$ are given by

$$\psi_{\ell,\pm} = \frac{1}{\sqrt{2}} \begin{pmatrix} \phi_\ell \\ \mp i \phi_{\ell-1} \end{pmatrix}, \quad (26)$$

corresponding to a positive and negative series of Landau levels with energies $E_\pm$ given by McClure (1956)

$$E_{\ell,\pm} = \pm \frac{\hbar v}{\lambda_B} \sqrt{2\ell}, \quad \ell \geq 1. \quad (27)$$

In graphene, the energy levels depend on the square root of the magnetic field B and the index ℓ , unlike a conventional two-dimensional semiconductor where the dependences are linear. In addition, there is a zero energy state with weight on the A sublattice only,

$$\psi_0 = \begin{pmatrix} \phi_0 \\ 0 \end{pmatrix}; \quad E_0 = 0. \quad (28)$$

At the second valley, K_- , the spectrum is degenerate with that of K_+ , but the role of the A and B sublattices is reversed. In particular, the zero energy state has weight only on the B sublattice.

Semiclassical quantization and Berry phase

The Landau level spectrum may be understood in terms of the Onsager semiclassical quantization (Xiao et al., 2010),

$$S(E) = \frac{2\pi}{\lambda_B^2} \left(\ell + \frac{1}{2} - \frac{\gamma}{2\pi} \right), \quad (29)$$

Fig. 5 Schematic of the Hall conductivity σ_{xy} vs carrier density n showing the integer quantum Hall effect for (A) a conventional two-dimensional semiconductor with zero Berry phase and twofold spin degeneracy, (B) monolayer graphene, (C) Bernal-stacked bilayer graphene.

where $S(E)$ is the area in reciprocal space enclosed by a contour at constant energy E , γ is Berry phase, and integer $\ell \geq 0$. For a conventional two-dimensional semiconductor with quadratic dispersion $E = \hbar^2 k^2 / (2m_*)$, effective mass m_* , then $S(E) = \pi k^2 = 2\pi m_* E / \hbar^2$. With zero Berry phase $\gamma = 0$, Eq. (29) then gives the usual harmonic oscillator relation, $E_\ell = \hbar\omega_c(\ell + 1/2)$, where the cyclotron frequency is $\omega_c = eB/m_*$.

For graphene, with $E = \pm \hbar v k$, then $S(E) = \pi k^2 = \pi E^2 / (\hbar^2 v^2)$. Berry phase $\gamma = \pi$ cancels the factor of $1/2$ on the right side of Eq. (29), giving $E_{\ell\pm} = \pm (\hbar v / \lambda_B) \sqrt{2\ell}$, in agreement with the fully quantum calculation Eq. (27). The spectrum of levels, without the zero point energy $\hbar\omega_c/2$, but with a level fixed with $E_0 = 0$, can be interpreted as a manifestation of Berry phase π .

Integer quantum Hall effect

In a conventional two-dimensional semiconductor with zero Berry phase, the Landau level spectrum is $E_\ell = \hbar\omega_c(\ell + 1/2)$ where $\omega_c = eB/m_*$ is the cyclotron frequency and integer $\ell \geq 0$. In the integer quantum Hall effect, quantized plateaus in the Hall conductivity σ_{xy} occur values of $M(2e^2/h)$ for twofold spin degeneracy, quantum of conductance e^2/h , and integer M . This is plotted in Fig. 5A showing σ_{xy} as a function of carrier density n . Each step as a function of density n corresponds to the crossing of a Landau level, and, as the capacity per level is $2eB/h$, the separation of plateaus on the density axis is $2eB/h$.

In monolayer graphene there is fourfold degeneracy due to twofold spin and twofold valley degeneracy, so quantized plateaus in the Hall conductivity are separated by steps of height $4e^2/h$. However, the plateaus occur at half-integer values of $4e^2/h$ (Gusynin and Sharapov, 2005; Haldane, 1988; Peres et al., 2006; Zheng and Ando, 2002), rather than the conventional integer ones,

$$\text{quantization : } \sigma_{xy} = -\frac{2M+1}{2} \left(\frac{4e^2}{h} \right), \quad (30)$$

for integer M , as observed experimentally (Novoselov et al., 2005; Zhang et al., 2005). This is plotted in Fig. 5B, where the plateaus are separated by the Landau level capacity $4eB/h$ on the density axis. This unusual sequencing of plateaus is sometimes called the 'half-integer' quantum Hall effect. It may be interpreted in terms of the level fixed with $E_0 = 0$ (as a manifestation of Berry phase π) which requires a step of height $4e^2/h$ in σ_{xy} as the density crosses zero between the electron and hole sides. Here we assumed that any splitting of the levels, due to breaking of spin or valley degeneracy, say, is negligible in comparison to temperature and level broadening.

Electronic properties of Bernal-stacked bilayer graphene

Bilayer graphene (or 'graphene bilayers') refers to two parallel monolayers of graphene. This might be two layers either side of a dielectric spacer (Gorbachev et al., 2012; Schmidt et al., 2008) or two layers in direct contact with weak atomic bonding between them. In the latter case, there are different possible ways to orient, or stack, the two layers with respect to each other. One option is twisted bilayer graphene (Cao et al., 2016; Kim et al., 2016; Rozhkov et al., 2016) resulting in either a periodic overall lattice with a very large unit cell, or a system with no periodicity. There are also two common ways which result in a periodic lattice with a small unit cell of lattice constant a , the same as that of a single layer. These are called Bernal stacking (or AB-stacking) (Bernal, 1924; McCann and Koshino, 2013; Novoselov et al., 2006; Rozhkov et al., 2016) and AA stacking (Lee et al., 2008b; Rozhkov et al., 2016), and Bernal stacking is the most energetically favorable of the two (Lebedeva et al., 2011; Mostaani et al., 2015).

If we consider each monolayer to lie in the horizontal (x - y) plane, then Bernal-stacked bilayer graphene (also known as AB-stacked bilayer graphene) is when half of the atoms are situated directly above or below an atom in the other layer. For AA stacking, every atom is directly above or below an atom in the other layer.

Fig. 6 Schematic of the lattice of Bernal-stacked bilayer graphene with A1 (white) and B1 (black) atomic sites on the lower layer, and A2 (black) and B2 (grey) atomic sites on the upper layer. (A) is a plan view, and the shaded rhombus represents a unit cell. (B) is a side view, indicating intralayer nearest-neighbor tight-binding parameter γ_0 and interlayer nearest-neighbor tight-binding parameter γ_1 .

Crystal structure

With A1, B1 atomic sites on the lower layer and A2, B2 sites on the upper layer, Bernal stacking (Bernal, 1924) describes the case when B1 and A2 sites lie directly below and above each other, but A1 and B2 have no such counterpart; they lie below or above the center of a hexagon in the other layer, Fig. 6. The result is a periodic lattice in the horizontal (x - y) plane with unit cell of the same area as that of monolayer graphene, Fig. 6A, but the unit cell now contains four atomic sites A1, B1, A2, B2. The interlayer spacing is about 3.35 Å.

Electronic band structure and tight-binding model

As with monolayer graphene, the electronic band structure near the Fermi level can be described by considering one $2p_z$ orbital per atom, i.e., four orbitals per unit cell for bilayer graphene. These yield four electronic bands. Assuming translational invariance within the graphene plane, it is possible to derive a Bloch Hamiltonian $H(\mathbf{k})$ as a four-component matrix in the basis of Bloch orbitals on A1, B1, A2, B2 sites, where $\mathbf{k} = (k_x, k_y)$ is the wave vector. The reciprocal lattice is the same as that of monolayer graphene: a hexagonal Bravais lattice with a hexagonal first Brillouin zone, as shown in Fig. 2A.

The ‘minimal model’ includes only coupling between nearest-neighbor intralayer sites (A1-B1 and A2-B2) with tight-binding parameter $\gamma_0 \approx 3$ eV (Dresselhaus and Dresselhaus, 2002; Saito et al., 1998), coupling between nearest-neighbor interlayer sites (B1-A2) with tight-binding parameter $\gamma_1 \approx 0.4$ eV (Dresselhaus and Dresselhaus, 2002; Kuzmenko et al., 2009; Li et al., 2009b; Zhang et al., 2008), and assuming atomic orbitals on adjacent atoms are orthogonal, the tight-binding Bloch Hamiltonian in basis A1, B1, A2, B2 (McCann and Fal’ko, 2006) is

Fig. 7 (A) Electronic band structure of Bernal-stacked bilayer graphene according to Eq. (31) with $\gamma_0 = 3$ eV, $\gamma_1 = 0.4$ eV, plotted along the line $k_y = 0$. Vertical dashed lines show the positions of the symmetry points Γ , K_+ and K_- . (B) Scaled up plot of the bands near the K_+ point, showing touching conduction and valence bands with quadratic dispersion at the valley center, and linear dispersion further away.

$$H(\mathbf{k}) = \begin{pmatrix} 0 & -\gamma_0 f(\mathbf{k}) & 0 & 0 \\ -\gamma_0 f^*(\mathbf{k}) & 0 & \gamma_1 & 0 \\ 0 & \gamma_1 & 0 & -\gamma_0 f(\mathbf{k}) \\ 0 & 0 & -\gamma_0 f^*(\mathbf{k}) & 0 \end{pmatrix},$$

where $f(\mathbf{k})$ is defined in Eq. (2). Each 2×2 block on the diagonal describes intralayer hopping, the off-diagonal 2×2 blocks account for interlayer coupling. The four energy bands are given by

$$E_{\pm}^{(\beta)}(\mathbf{k}) = \pm \frac{\gamma_1}{2} \left(\sqrt{1 + \frac{4\gamma_0^2 |f(\mathbf{k})|^2}{\gamma_1^2}} + \beta \right), \quad (31)$$

where $\beta = \pm 1$. They are plotted in Fig. 7 along the line $k_y = 0$. In general, Fig. 7A, the bands are two copies of the monolayer bands, Fig. 2B, split by the interlayer coupling parameter γ_1 . As in monolayer, there is no band gap, but a degeneracy at the Fermi level at the two K points (K_+ and K_-), Fig. 7B.

At the two valley centers, K_+ and K_- , $f(\mathbf{k}_{\xi}) = 0$. At these points, Eq. (31) shows that two bands with $\beta = 1$ are $E_{\pm}^{(1)}(\mathbf{k}_{\xi}) = \pm \gamma_1$ and split away from the Fermi level, whereas the two bands with $\beta = -1$ are $E_{\pm}^{(-1)}(\mathbf{k}_{\xi}) = 0$, touching at the Fermi level. Near the valley centers $\mathbf{k} = \mathbf{k}_{\xi} + \mathbf{q}$, for $|\mathbf{q}|a \ll 1$, then $\gamma_0 |f(\mathbf{k})| \approx \hbar v |\mathbf{q}|$ and Eq. (31) interpolates between quadratic dispersion at the valley center to linear dispersion at larger energy,

$$E_{\pm}^{(-1)} \approx \begin{cases} \pm \hbar^2 |\mathbf{q}|^2 / (2m^*) & \text{for } 2\hbar v |\mathbf{q}| \ll \gamma_1 \\ \pm \hbar v |\mathbf{q}| & \text{for } 2\hbar v |\mathbf{q}| \gg \gamma_1 \end{cases}, \quad (32)$$

where the effective mass is very light, $m^* = \gamma_1 / (2v^2) \approx 0.04m_e$ where m_e is the free electron mass. Interlayer coupling γ_1 introduces an additional energy scale as compared to monolayer graphene. There is a corresponding length scale $\ell_{\perp} = \hbar v / \gamma_1$ with value $\ell_{\perp} = \sqrt{3}\gamma_0 a / (2\gamma_1) \approx 21 \text{ \AA}$ so that $\ell_{\perp} \approx 9a$. Hence the quadratic dispersion at long wavelength described by Eq. (32) occurs for $\ell_{\perp} |\mathbf{q}| \ll 1$.

Effective-mass model, pseudospin and chirality

Near the valley center, two bands $E_{\pm}^{(1)}(\mathbf{k}_{\xi}) = \pm \gamma_1$ are split away from $E = 0$. They arise predominantly from the interlayer coupling γ_1 between orbitals on the B1 and A2 sites, creating a dimer with a bonding and anti-bonding pair of energies.

The two bands that touch at the valley center at $E = 0$ arise from orbitals on the A1 and B2 sites (the ones without a counterpart in the other layer directly above or below), and the quadratic dispersion near the valley center may be understood as effective coupling between these orbitals. An electron hopping from A1 to B2 involves a path via the strongly coupled B1-A2 dimer: intralayer hopping on each layer (e.g., A1 to B1 and A2 to B2) gives a quadratic dispersion with the interlayer hopping (B1 to A2) contributing to the

effective mass $m_* = \gamma_1/(2v^2)$. This process may be described by an effective 2×2 Bloch Hamiltonian in the basis of orbitals of A1 and B2 sites only. It is obtained by eliminating the B1 and A2 components (the matrix equation $H(\mathbf{k})\psi_{\pm}^{(\beta)}(\mathbf{k}) = E_{\pm}^{(\beta)}(\mathbf{k})\psi_{\pm}^{(\beta)}(\mathbf{k})$ may be viewed as four simultaneous equations) and using the substitution $\gamma_0 f(\mathbf{k}_\xi + \mathbf{q}) = -\hbar v(\xi q_x - i q_y)$ with $\ell_\perp |\mathbf{q}| \ll 1$.

Hence, in the A1-B2 basis, the low-energy effective Hamiltonian (McCann and Fal'ko, 2006) is

$$H_\xi^{(2)}(\mathbf{q}) = -\frac{\hbar^2}{2m_*} \begin{pmatrix} 0 & (\xi q_x - i q_y)^2 \\ (\xi q_x + i q_y)^2 & 0 \end{pmatrix}, \quad (33)$$

where the superscript (2) is used to stress that this is for bilayer graphene. The effective mass model $H_\xi^{(2)}(\mathbf{q})$ describes the quadratic dispersion of the gapless energy bands near the valleys and the Fermi level ($E = 0$),

$$E_\pm(\mathbf{q}) = \pm \frac{\hbar^2 |\mathbf{q}|^2}{2m_*}. \quad (34)$$

Corresponding eigenstates can be conveniently written as

$$\psi_\pm = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ \mp e^{2i\xi\phi} \end{pmatrix}, \quad (35)$$

where ϕ is the polar angle of the wave vector, $q_x = |\mathbf{q}| \cos \phi$, $q_y = |\mathbf{q}| \sin \phi$. Taking into account twofold spin degeneracy and twofold valley degeneracy, the isotropic dispersion Eq. (5) yields a density of states per unit energy per unit area at low energy given by

$$g(E) = \frac{2m_*}{\pi \hbar^2}, \quad (36)$$

which is independent of energy E , and Fermi velocity $v_F = \hbar q_F/m_*$ where q_F is the magnitude of the Fermi wavevector measured from the valley center.

The effective mass model Hamiltonian Eq. (33) is a generalization of the Dirac effective-mass model of monolayer graphene Eq. (4), and there is a pseudospin related to the A1, B2 sublattice degree of freedom. With Pauli matrices in the sublattice space, the low-energy effective Hamiltonian Eq. (33) may be written as

$$H_\xi^{(2)}(\mathbf{q}) = -\frac{\hbar^2}{2m_*} \left[(q_x^2 - q_y^2) \sigma_x + 2\xi q_x q_y \sigma_y \right]. \quad (37)$$

For a vector of Pauli spin matrices $\boldsymbol{\sigma} = (\sigma_x, \sigma_y, \sigma_z)$ in the A1, B2 space, its expectation value with respect to the eigenstates Eq. (35) is $\langle \psi_\pm | \boldsymbol{\sigma} | \psi_\pm \rangle = \pm \hat{\mathbf{n}}_2$ where the unit vector $\hat{\mathbf{n}}_2$ is

$$\hat{\mathbf{n}}_2 = -(\cos 2\phi, \xi \sin 2\phi, 0). \quad (38)$$

Hence the Hamiltonian may be further written as

$$H_\xi^{(2)}(\mathbf{q}) = \frac{\hbar^2 |\mathbf{q}|^2}{2m_*} \boldsymbol{\sigma} \cdot \hat{\mathbf{n}}_2, \quad (39)$$

which emphasizes that electrons in bilayer graphene are chiral with the pseudospin direction linked to that of the electronic wave vector. However, in bilayer the pseudospin Eq. (38) turns twice as quickly in the plane as the wave vector.

The two-component effective Hamiltonians Eqs. (4 and 33) can be generalized for arbitrary positive integer $N \geq 1$ (Novoselov et al., 2006) as

$$H_\xi^{(N)}(\mathbf{q}) = -\gamma_1 (-\ell_\perp)^N \begin{pmatrix} 0 & (\xi q_x - i q_y)^N \\ (\xi q_x + i q_y)^N & 0 \end{pmatrix}, \quad (40)$$

where $\ell_\perp = \hbar v/\gamma_1$. This Hamiltonian occurs as a contribution to the low-energy description of surface states in rhombohedral graphite with a finite number of layers N (Guinea et al., 2006; Koshino and McCann, 2009; Mañes et al., 2007; Min and MacDonald, 2008; Slizovskiy et al., 2019). Its eigenstates, with energy $E_\pm(\mathbf{q}) = \pm \gamma_1 (\ell_\perp |\mathbf{q}|)^N$, have expectation of pseudospin given by $\langle \psi_\pm | \boldsymbol{\sigma} | \psi_\pm \rangle = \pm \hat{\mathbf{n}}_N$ where the unit vector $\hat{\mathbf{n}}_N$ is

$$\hat{\mathbf{n}}_N = (-\xi)^{N+1} (\xi \cos N\phi, \sin N\phi, 0). \quad (41)$$

Hence the Hamiltonian may be written (McCann and Fal'ko, 2006; Novoselov et al., 2006) as

$$H_\xi^{(N)}(\mathbf{q}) = \gamma_1 (\ell_\perp |\mathbf{q}|)^N \boldsymbol{\sigma} \cdot \hat{\mathbf{n}}_N, \quad (42)$$

describing chiral electrons where the pseudospin turns N times more quickly than the wavevector in the graphene plane.

Symmetries

In the absence of external perturbations, bilayer graphene satisfies space and time inversion symmetries. For the low-energy effective Hamiltonian Eq. (33), these are expressed as

$$\text{space inversion : } \sigma_x H_{\xi}^{(2)}(\mathbf{q}) \sigma_x = H_{-\xi}^{(2)}(-\mathbf{q}), \quad (43)$$

$$\text{time inversion : } \left(H_{\xi}^{(2)}(\mathbf{q}) \right)^* = H_{-\xi}^{(2)}(-\mathbf{q}). \quad (44)$$

In the minimal model, with nearest-neighbor intralayer and interlayer hopping, the low-energy Hamiltonian also satisfies chiral symmetry,

$$\text{chiral : } \sigma_z H_{\xi}^{(2)}(\mathbf{q}) \sigma_z = -H_{\xi}^{(2)}(\mathbf{q}), \quad (45)$$

which ensures electron-hole symmetry of the electronic spectrum, as shown in Fig. 7. Chiral symmetry may be combined with time-inversion symmetry to give charge conjugation symmetry $\sigma_z (H_{\xi}^{(2)}(\mathbf{q}))^* \sigma_z = -H_{-\xi}^{(2)}(-\mathbf{q})$.

Berry phase 2π

For bilayer graphene, the eigenstates Eq. (35) have Berry connection $\mathbf{A}_{\pm}(\mathbf{q}) = -\xi \hat{\mathbf{e}}_{\phi} / |\mathbf{q}|$ where $\hat{\mathbf{e}}_{\phi}$ is the unit vector of polar angle π . The Berry phase for a closed path in reciprocal space around a single valley is

$$\gamma_{\pm} = \oint_C \mathbf{A}_{\pm}(\mathbf{q}) \cdot d\mathbf{q} = -\xi 2\pi, \quad (46)$$

and, hence, bilayer graphene is sometimes described as having Berry phase 2π (McCann and Fal'ko, 2006; Novoselov et al., 2006). Berry phase, however, is only gauge invariant modulo 2π so the Berry phase in bilayer graphene is zero. Nevertheless, the factor of $N = 2$ is used to describe the degree of chirality in bilayer as demonstrated by the pseudospin vector Eq. (38). In the same way, the Hamiltonian Eq. (40) is said to have Berry phase $N\pi$, reflecting the behavior of the pseudospin in Eq. (41).

Trigonal warping and other tight-binding parameters

The Hamiltonians Eqs. (31 and 33) are written in the minimal model which includes only nearest-neighbor intralayer γ_0 and interlayer γ_1 coupling. However, the presence of two layers with interlayer coupling allows for more tight-binding parameters than in monolayer graphene. Authors often adopt the Slonczewski-Weiss-McClure model (Dresselhaus and Dresselhaus, 2002; McClure, 1957, 1960; Slonczewski and Weiss, 1958) which is a seven-parameter model of bulk Bernal-stacked graphite. With only two layers, Bernal-stacked bilayer does not allow for all seven parameters (such as those describing next-nearest layer hopping), but the 'skew' interlayer hoppings parameterized by γ_3 and γ_4 can be important.

Parameter γ_3 (Dresselhaus and Dresselhaus, 2002; McCann and Fal'ko, 2006) describes interlayer coupling between A1 and B2 orbitals which form the basis for the low-energy Hamiltonian Eq. (33). As it connects them directly, it gives a contribution at linear order in $\mathbf{q}$ to Eq. (33),

$$H_{\xi}^{(2)}(\mathbf{q}) = -\frac{\hbar^2}{2m_*} \begin{pmatrix} 0 & (\xi q_x - i q_y)^2 \\ (\xi q_x + i q_y)^2 & 0 \end{pmatrix} + \hbar v_3 \begin{pmatrix} 0 & (\xi q_x + i q_y) \\ (\xi q_x - i q_y) & 0 \end{pmatrix}, \quad (47)$$

where $v_3 = \sqrt{3}a\gamma_3/(2\hbar)$ has physical dimensions of velocity, and $|v_3| \approx 10^5 \text{ m s}^{-1}$. Corresponding eigenvalues are

$$E_{\pm}(\mathbf{q}) = \pm \sqrt{(\hbar v_3 |\mathbf{q}|)^2 - \frac{\xi \hbar^3 v_3 |\mathbf{q}|^3}{m_*} \cos(3\phi) + \left(\frac{\hbar^2 |\mathbf{q}|^2}{2m_*} \right)^2}. \quad (48)$$

The factor of $\cos(3\phi)$ introduces trigonal warping of a constant energy contour (which would be circular otherwise, Eqs. (32 and 34)). Since the γ_3 term in the Hamiltonian is linear in wavevector $\mathbf{q}$, the trigonal warping tends to be pronounced at low energy (as opposed to trigonal warping in monolayer graphene). As the energy is reduced, the trigonal distortion increases. At energy $E_L = (\gamma_1/4)(\gamma_3/\gamma_0)^2 \approx 1 \text{ meV}$, there is a Lifshitz transition in which the Fermi surface at each K point breaks into four separate contours: a central contour at the valley center with three elliptically-shaped contours at distance $|\mathbf{q}| \approx \gamma_1 v_3 / (\hbar v^2)$ and separated by angles of $2\pi/3$. The orientation of trigonal warping depends on the sign of the product $\gamma_1 \gamma_3$, and scanning tunneling microscope measurements (Joucken et al., 2020) have determined that $\gamma_3 = -0.3 \text{ eV}$. This means that the orientation of trigonal warping at low energy, due to γ_3 , is opposite to that of monolayer graphene, Fig. 3. At high energy, e.g., $E \gg \gamma_1$, the orientation of trigonal warping will be the same as that in monolayer, because the cause is the same (higher order in $\mathbf{q}$ terms in the expansion of $f(\mathbf{k}_{\xi} + \mathbf{q})$).

Parameter γ_4 (Dresselhaus and Dresselhaus, 2002) describes interlayer coupling between A1 and A2 orbitals, and between B1 and B2 orbitals. It gives a contribution to the A1-B2 low-energy Hamiltonian of the form

$$H_{\gamma_4}(\mathbf{q}) = \frac{\gamma_4 \hbar^2 |\mathbf{q}|^2}{\gamma_0 m^*} \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}. \quad (49)$$

Taken with the minimal model low-energy Hamiltonian Eq. (33), this gives eigenvalues as

$$E_{\pm}(\mathbf{q}) = \frac{\gamma_4 \hbar^2 |\mathbf{q}|^2}{\gamma_0 m^*} \pm \frac{\hbar^2 |\mathbf{q}|^2}{2m^*}. \quad (50)$$

Since γ_4 connects A atoms to other A atoms, and B atoms to other B atoms, H_{γ_4} is diagonal in the sublattice space, and it breaks chiral symmetry Eq. (45). Thus, the energy spectrum Eq. (50) breaks electron-hole symmetry. However, for $\gamma_4 \approx 0.1$ eV (Kuzmenko et al., 2009; Malard et al., 2007; Zhang et al., 2008), the factor $\gamma_4/\gamma_0 \approx 0.03$, so the influence of γ_4 is generally quite small.

Band gap tunable with an electric field

Band structure with a band gap

As with monolayer graphene, an external gate voltage may be used to tune the carrier density in bilayer graphene. However, such an external potential will also introduce asymmetry between the electrostatic potentials of the two layers, and this asymmetry creates a tunable band gap in the bilayer energy spectrum (Castro et al., 2007; McCann, 2006; McCann and Fal'ko, 2006; McCann and Koshino, 2013; Min et al., 2007; Ohta et al., 2006; Oostinga et al., 2008).

If we parameterize the difference in energy between the layers as U , then the lower layer is at energy $-U/2$ and the upper layer at $U/2$. Then, the low-energy effective Hamiltonian in the $A1, B2$ basis Eq. (33) is modified (McCann and Fal'ko, 2006) as

$$H_{\xi}^{(2)}(\mathbf{q}) = -\frac{\hbar^2}{2m^*} \begin{pmatrix} 0 & (\xi q_x - i q_y)^2 \\ (\xi q_x + i q_y)^2 & 0 \end{pmatrix} - \frac{U}{2} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad (51)$$

with energies

$$E_{\pm}(\mathbf{q}) = \pm \sqrt{\frac{U^2}{4} + \left(\frac{\hbar^2 |\mathbf{q}|^2}{2m^*}\right)^2}, \quad (52)$$

and band gap $E_g = E_+(0) - E_-(0) = |U|$. Corresponding eigenstates are

$$\psi_{\pm} = \sqrt{\frac{E_{\pm} - U/2}{2E_{\pm}}} \begin{pmatrix} 1 \\ -\frac{\hbar^2 |\mathbf{q}|^2}{2m^*(E_{\pm} - U/2)} e^{2i\xi\phi} \end{pmatrix}, \quad (53)$$

The first component of the eigenstates Eq. (53) describes the amplitude on site $A1$ in the first layer, the second component describes the amplitude on site $B2$ in the second layer. Thus, the presence of the asymmetry parameter U in the eigenstates Eq. (53) accounts for different carrier densities n_1 and n_2 on the two layers, where the total carrier density is $n = n_1 + n_2$. As the energy spectrum is isotropic around the valley center Eq. (52), the densities on each layer may be determined by integrating over a circular Fermi surface,

$$n_{1(2)} = \frac{2}{\pi} \int |\psi_{A1(B2)}(q)|^2 q dq \quad (54)$$

where q is the magnitude of the wavevector, and $\psi_{A1(B2)}$ is the component of the eigenstate on the $A1$ ($B2$) site. A factor of four is included to account for spin and valley degeneracy.

If we consider a partially filled conduction band, then we can integrate Eq. (54) for $0 < q < q_F$, where q_F is the magnitude of the Fermi wavevector. The filled valence band can be included by integrating for $0 < q < q_{\max}$, where $q_{\max} = \gamma_1/(\hbar v)$ is an ultraviolet cutoff, equivalent to a large density $n_{\perp}$. Then, the layer densities (Fogler and McCann, 2010; McCann, 2006; McCann and Koshino, 2013) are

$$n_{1(2)} \approx \frac{n}{2} \mp \frac{n_{\perp} U}{4\gamma_1} \ln \left(\frac{|n|}{2n_{\perp}} + \frac{1}{2} \sqrt{\left(\frac{n}{n_{\perp}}\right)^2 + \left(\frac{U}{2\gamma_1}\right)^2} \right), \quad (55)$$

where the minus (plus) sign is for the first (second) layer, n is the total carrier density (as measured from the Dirac point), and $n_{\perp}$ is a characteristic density scale,

$$n = \frac{q_F^2}{\pi}; \quad n_{\perp} = \frac{\gamma_1^2}{\pi \hbar^2 v^2}. \quad (56)$$

With $\gamma_1 = 0.4$ eV and $v = 1.0 \times 10^6$ m s⁻¹, then $n_{\perp} = 1.2 \times 10^{13}$ cm⁻². The dependence of the layer densities on the asymmetry parameter, Eq. (55), is illustrated in Fig. 8A.

Fig. 8 (A) Layer densities n_1 (solid line) and n_2 (dashed) as a function of the asymmetry parameter U for fixed total density $n = n_1 + n_2 = n_\perp/2$ according to Eq. (55). (B) Band gap $E_g = |U|\gamma_1/\sqrt{\gamma_1^2 + U^2}$ as a function of total density n with asymmetry parameter U determined by numerical solution of Eq. (61) with screening parameter $\Lambda = 1$ (solid line). The dashed line shows E_g with $U = U_{\text{ext}}$ neglecting screening. Note that n is proportional to the external gate voltage V_g , Eq. (57).

Self-consistent screening

The layer carrier densities n_1, n_2 , Eq. (55), are dependent on the total carrier density n , and the difference in layer energies U . External gate potentials will modify n and U , and hence n_1, n_2 , but, at the same time, the layer charge densities $\sigma_1 = -en_1$ and $\sigma_2 = -en_2$ will screen the gate potentials. This screening may be modeled simply using a Hartree approximation (i.e., neglecting exchange and correlations between electrons), and the resulting equations solved self-consistently to determine the dependence of the layer densities and band gap on the external potentials.

We consider the situation with a back gate, voltage V_g , of infinite extent in the x - y plane and located at $z = -d$. Bilayer graphene is modeled as two narrow layers, of infinite extent in the x - y plane and located at $z = \pm c_0/2$, where c_0 is the layer separation and $c_0 \ll d$. Using Gauss's law, the gate voltage V_g is related to the layer carrier densities and interlayer asymmetry (McCann, 2006) as

$$n = \frac{\epsilon_0 \epsilon_g}{ed} V_g, \quad (57)$$

$$U = \frac{e^2 c_0}{\epsilon_0 \epsilon_r} n_2, \quad (58)$$

where we use SI units and denote electronic charge as $-e$ with $e > 0$. The dielectric constant of the space between the gate and bilayer is ϵ_g , that of the space between the two bilayer layers is ϵ_r . Eq. (57) shows that the total density n is proportional to the gate voltage V_g , as in monolayer, Eq. (21). Eq. (58) relates the asymmetry parameter U to the density n_2 on the layer furthest from the gate; by Gauss's law, the charge density $\sigma_2 = -en_2$ accounts for the interlayer electric field $U/(ec_0)$.

We rewrite the expression for the interlayer asymmetry (McCann and Koshino, 2013) as

$$U = U_{\text{ext}} + \Lambda \gamma_1 \frac{(n_2 - n_1)}{n_\perp}, \quad (59)$$

where the first term, U_{ext} , describes the value of U in the absence of screening, i.e., as if $n_2 = n_1 = n/2$, and the second term describes screening where Λ is the dimensionless screening parameter,

$$U_{\text{ext}} = \frac{e \epsilon_g c_0}{2 \epsilon_r d} V_g, \quad \Lambda = \frac{e^2 c_0 n_\perp}{2 \gamma_1 \epsilon_0 \epsilon_r}. \quad (60)$$

With interlayer spacing $c_0 = 3.35 \text{ \AA}$ and $\epsilon_r \sim 1$, then $\Lambda \sim 1$ which indicates that screening is important. Substituting the expression for layer densities, Eq. (55), into that for asymmetry U , Eq. (59), gives the density dependence of the asymmetry parameter (and band gap) (Fogler and McCann, 2010; McCann and Koshino, 2013) as

$$\frac{U}{U_{\text{ext}}} \approx \left[1 - \frac{\Lambda}{2} \ln \left(\frac{|n|}{2n_\perp} + \frac{1}{2} \sqrt{\left(\frac{n}{n_\perp} \right)^2 + \left(\frac{U}{2\gamma_1} \right)^2} \right) \right]^{-1}. \quad (61)$$

With $U_{\text{ext}} = \Lambda\gamma_1 n/n_\perp$, and using $|U| \gg \gamma_1$ for density that is not too small, then this may be simplified to give an explicit formula (McCann, 2006),

$$U \approx \frac{\Lambda\gamma_1 n}{n_\perp} \left[1 - \frac{\Lambda}{2} \ln \left(\frac{|n|}{n_\perp} \right) \right]^{-1}. \quad (62)$$

At low density $|n| \ll n_\perp$, the logarithmic term is large, indicating the important role of screening. At high density $|n| \sim n_\perp$, however, the logarithm is small and $U \approx U_{\text{ext}} = \Lambda\gamma_1 n/n_\perp$ is linear in density (and gate voltage). Here we only used the low-energy two-component Hamiltonian Eq. (51); use of the full four-component model Eq. (31) shows that the band gap E_g depends on the asymmetry U as $E_g = |U|\gamma_1/\sqrt{\gamma_1^2 + U^2}$. Then the band gap saturates, $E_g \rightarrow \gamma_1$, for large asymmetry $|U| \gg \gamma_1$. The dependence of E_g on n is illustrated in Fig. 8B (where n is proportional to V_g , Eq. (57)).

Integer quantum Hall effect

In the presence of a perpendicular magnetic field $\mathbf{B} = (0, 0, -B)$ with vector potential $\mathbf{A} = (0, -Bx, 0)$, the low-energy Hamiltonian Eq. (33) at the first valley may be written (McCann and Fal'ko, 2006) as

$$H_+^{(2)} = \hbar\omega_c \begin{pmatrix} 0 & (a^\dagger)^2 \\ a^2 & 0 \end{pmatrix}, \quad (63)$$

where $\omega_c = eB/m_*$, and $a^\dagger, a$ are raising and lowering operators Eqs. (24 and 25). Eigenvalues and eigenstates are given by

$$\begin{aligned} \ell \geq 2 : \quad E_{\ell,\pm} &= \pm \hbar\omega_c \sqrt{\ell(\ell-1)}, \quad \psi_{\ell,\pm} = \frac{1}{\sqrt{2}} \begin{pmatrix} \phi_\ell \\ \pm \phi_{\ell-2} \end{pmatrix}, \\ \ell = 1 : \quad E_1 &= 0, \quad \psi_1 = \begin{pmatrix} \phi_1 \\ 0 \end{pmatrix}, \\ \ell = 0 : \quad E_0 &= 0, \quad \psi_0 = \begin{pmatrix} \phi_0 \\ 0 \end{pmatrix}. \end{aligned}$$

The Landau levels depend linearly on magnetic field and, for $\ell \gg 1$, linearly on the index ℓ , in contrast to monolayer graphene where there are square root dependences. In bilayer, however, there are two zero energy levels, E_1 and E_0 , with states having weight on the A1 sublattice only at valley K_+ . At the second valley, K_- , the spectrum is degenerate with that of K_+ , but the role of the A1 and B2 sublattices is reversed, so that the zero energy states have weight only on the B2 sublattice.

The presence of two zero energy levels, E_1 and E_0 , gives eightfold degeneracy of levels at zero energy, including spin and valley degeneracy. This is manifested in the integer quantum Hall effect, shown in Fig. 5C. Landau levels at nonzero energy are fourfold degenerate, due to spin and valley, and quantized plateaus in the Hall conductivity occur at integer values of $4e^2/h$,

$$\text{quantization} : \sigma_{xy} = -M \left(\frac{4e^2}{h} \right), \quad (64)$$

where M is integer, but $M \neq 0$ (McCann and Fal'ko, 2006), as observed experimentally (Novoselov et al., 2006). The eightfold degenerate levels with $E_1 = E_0 = 0$ require a step of height $8e^2/h$ in σ_{xy} as the density crosses zero between the electron and hole sides. Here we assumed that any splitting of the levels, due to breaking of spin or valley degeneracy, say, is negligible in comparison to temperature and level broadening.

Electronic properties of AA-stacked bilayer graphene

Crystal structure

With A1, B1 atomic sites on the lower layer and A2, B2 sites on the upper layer, AA stacking (Lee et al., 2008b; Rozhkov et al., 2016) describes the case when the two lattices are exactly aligned, i.e., A1 and A2 sites lie directly below and above each other, and B1 and B2 sites lie directly below and above each other, Fig. 9. The result is a periodic lattice in the horizontal (x - y) plane with unit cell of the same area as that of monolayer graphene, Fig. 9A. The unit cell now contains four atomic sites A1, B1, A2, B2.

Electronic band structure and tight-binding model

The electronic band structure near the Fermi level can be described by considering one $2p_z$ orbital per atom, i.e., four orbitals per unit cell for AA-stacked bilayer graphene. These yield four electronic bands. Assuming translational invariance within the graphene plane, it is possible to derive a Bloch Hamiltonian $H(\mathbf{k})$ as a four-component matrix in the basis of Bloch orbitals on A1, B1, A2, B2

Fig. 9 Schematic of the lattice of AA-stacked bilayer graphene with A1 (white) and B1 (black) atomic sites on the lower layer, and A2 (white) and B2 (black) atomic sites on the upper layer. (A) is a plan view, with the atoms of the second layer lying directly above their counterparts in the first layer, and the shaded rhombus represents a unit cell. (B) is a side view, indicating intralayer nearest-neighbor tight-binding parameter γ_0 and interlayer nearest-neighbor tight-binding parameter γ_1 .

sites, where $\mathbf{k} = (k_x, k_y)$ is the wave vector. The reciprocal lattice is the same as that of monolayer graphene: a hexagonal Bravais lattice with a hexagonal first Brillouin zone, as shown in Fig. 2A.

Including only coupling between nearest-neighbor intralayer sites (A1-B1 and A2-B2) with tight-binding parameter $\gamma_0 \approx 3$ eV, coupling between nearest-neighbor interlayer sites (A1-A2 and B1-B2) with tight-binding parameter $\gamma_1 \approx 0.3$ eV, and assuming atomic orbitals on adjacent atoms are orthogonal, the tight-binding Bloch Hamiltonian in basis A1, B1, A2, B2 is (Rozhkov et al., 2016)

$$H(\mathbf{k}) = \begin{pmatrix} 0 & -\gamma_0 f(\mathbf{k}) & \gamma_1 & 0 \\ -\gamma_0 f^*(\mathbf{k}) & 0 & 0 & \gamma_1 \\ \gamma_1 & 0 & 0 & -\gamma_0 f(\mathbf{k}) \\ 0 & \gamma_1 & -\gamma_0 f^*(\mathbf{k}) & 0 \end{pmatrix},$$

where $f(\mathbf{k})$ is defined in Eq. (2).

The basis can be rewritten as a pair of two-component bases, $(A1 + \alpha A2)/\sqrt{2}$, $(B1 + \alpha B2)/\sqrt{2}$, with $\alpha = 1$ or $\alpha = -1$. Then, the Hamiltonian is split into two independent 2×2 blocks,

$$H^{(\alpha)}(\mathbf{k}) = \begin{pmatrix} \alpha\gamma_1 & -\gamma_0 f(\mathbf{k}) \\ -\gamma_0 f^*(\mathbf{k}) & \alpha\gamma_1 \end{pmatrix}, \quad (65)$$

with energy bands given by

$$E_{\pm}^{(\alpha)}(\mathbf{k}) = \alpha\gamma_1 \pm \gamma_0 |f(\mathbf{k})|. \quad (66)$$

They are plotted in Fig. 10 along the line $k_y = 0$. The bands are two exact copies of the monolayer bands, Fig. 2B, split by the interlayer coupling parameter γ_1 , and the split linear bands are evident near the Fermi level at the two K points (K_+ and K_-),

Fig. 10 (A) Electronic band structure of AA-stacked bilayer graphene according to Eq. (66) with $\gamma_0 = 3$ eV, $\gamma_1 = 0.4$ eV, plotted along the line $k_y = 0$. Vertical dashed lines show the positions of the symmetry points Γ , K_+ and K_- . (B) Scaled up plot of the bands near the K_+ point, showing crossing of linear bands near the valley center.

Fig. 10B. This means that many properties of AA-stacked bilayer graphene may be related to those of monolayer graphene, at least in the approximation that uses only nearest-neighbor tight-binding parameters.

Conclusion

This chapter focused on the electronic properties of graphene, including Dirac-like chiral charge carriers with a linear electronic dispersion in monolayer graphene, and massive chiral charge carriers with a quadratic dispersion in bilayer graphene. Since the isolation of graphene by Geim, Novoselov and colleagues in 2004 (Novoselov et al., 2004), it has been the subject of intense research. Some of the topics not covered here, with references for further reading, are spectroscopy and imaging including Raman spectroscopy, scanning tunneling microscopy, photoemission and optical spectroscopy (Andrei et al., 2012; Basov et al., 2014; Ferrari, 2007; Malard et al., 2009; Orlita and Potemski, 2010), phonons and strain (Castro Neto et al., 2009), electronic transport (Castro Neto et al., 2009; Das Sarma et al., 2011; Peres, 2010), quantum dots and nanoribbons (Abergel et al., 2010; Castro Neto et al., 2009), disorder (Abergel et al., 2010; Castro Neto et al., 2009), magnetism (Yazyev, 2010), spintronics and pseudospintronics (Pesin and MacDonald, 2012), orbital magnetism (Castro Neto et al., 2009; Koshino and Ando, 2007), Andreev reflection (Beenakker, 2008), and, finally, many-body effects (Abergel et al., 2010; Basov et al., 2014; Castro Neto et al., 2009).

Abstract

This article is an introduction to the nontrivial topological properties associated with the special band structure in the electron systems with strong spin-orbital coupling, where a new topological phase known as topological insulator emerges. A Z_2 topological invariant can distinguish a topological insulator from a trivial band insulator in time-reversal invariant systems. The theoretically predicted quantum spin Hall effect and three dimensional topological insulators have been discovered experimentally. We provide an introduction to the understandings of topological insulating state, interaction effect and fractional quantum spin Hall effect, as well as their numerical identification.

Key points

- A new topological state emerges in the time-reversal invariant system with spin-orbital coupling.
- A Z_2 topological index provides a topological characterization of the topological insulator.
- A quantum spin Hall effect naturally emerges for topological insulators.
- A topological insulator has a nonzero spin Chern number and a projected spin gap for the occupied bands.
- A fractional topological insulator can emerge in interacting system.
- A chiral system liquid is an example of the bosonic fractional quantum Hall effects in spin systems, which can be detected by spin pumping and quantized Chern number.

Introduction and overview

The quantum Hall effect is one of the most remarkable phenomena discovered in two-dimensional (2D) electron systems subject to a strong perpendicular magnetic field. The GaAs/AlGaAs heterojunction grown by molecular beam epitaxy is a typical example of material realization of this system. If made sufficiently pure, such systems can exhibit both integer and fractional quantum Hall effects (IQHE/FQHE) at low enough temperature (Prange and Girvin, 1990; Klitzing et al., 1980; Tsui et al., 1982), which conduct quantized Hall currents without any dissipation. Both IQHE and FQHE can be characterized by the topological Chern number associated with either energy band or many-body ground state. The charge Hall conductance is found to be determined by the Chern number of the filled bands (or many-body Chern number), which is known as the Thouless-Kohmoto-Nightingaleden Nijss (TKNN) integer (Thouless et al., 1982; Qian Niu et al., 1985).

While the IQHE is usually observed in a strong magnetic field, Haldane first proposed a lattice model of spinless fermion with the complex hoppings breaking time-reversal symmetry, which has nontrivial topological bands carrying nonzero Chern numbers that can lead to the IQHE without a magnetic field (Haldane, 1988). Interestingly, when considering spin degrees of freedom, the two-component Haldane model can be more naturally realized in realistic systems, where the complex hoppings can be induced by the intrinsic spin-orbital coupling and such systems also recover time-reversal symmetry.

In such electron systems with strong spin-orbital coupling, a new class of nontrivial insulators has been theoretically identified as a time-reversal invariant 2D electronic phase (Kane and Mele, 2005a,b; Andrei Bernevig and Zhang, 2006; Andrei Bernevig et al., 2006; Sheng et al., 2006, 2005; Qi et al., 2006a,b; Liang and Kane, 2006; Congjun et al., 2006; Roy, 2009; Moore and Balents, 2007), which has a bulk energy gap generated by spin-orbital coupling. It is known as the topological insulator with a Z_2 topological invariant (Kane and Mele, 2005a; Qi et al., 2006a; Liang and Kane, 2006; Roy, 2009; Moore and Balents, 2007), which is distinguished from trivial insulator by the fact that the edge of a topological insulator contains a time-reversal symmetry protected pair of gapless edge modes with opposite chiralities. Such protected edge modes and the resulting quantum spin Hall effect (QSHE) have been observed in the HgTe quantum wells (König et al., 2007) and many other systems (Hasan and Kane, 2010). Graphene

and other electron systems with intrinsic spin-orbital coupling have been used as examples for illustrating the nontrivial topological insulator with dissipationless QSHE (Andrei Bernevig and Zhang, 2006; Kane and Mele, 2005b; Sheng et al., 2005; Qi et al., 2006a,b), where the spin-orbital coupling induces a spin-dependent effective magnetic field.

In this chapter, we will introduce the lattice model, the bulk topological characterization and its connection with the edge spin polarization. We will also discuss the robustness of the QSHE against the effect of disorder and Rashba spin coupling. We will further discuss the fractional quantum spin Hall effect (FQSHE) (Levin and Stern, 2009; Maciejko et al., 2010; Swingle et al., 2011; Neupert et al., 2011; Chen and Yang, 2012; Ghaemi et al., 2012) and FQHE in spin systems (Kalmeyer and Laughlin, 1987; Wen et al., 1989; He et al., 2014; Gong et al., 2014; Bauer et al., 2014), both can be characterized by many-body Chern numbers (Thouless et al., 1982; Qian Niu et al., 1985; Sheng et al., 2006, 2003a).

Topological insulator and quantum spin Hall effect

We begin with a single-particle Hamiltonian with spin-orbital couplings and on-site random disorder on the honey-comb lattice (Haldane, 1988; Kane and Mele, 2005a; Sheng et al., 2006):

$$H_0 = -t \sum_{\langle ij \rangle} c_i^\dagger c_j + \frac{2i}{\sqrt{3}} V_{SO} \sum_{\langle\langle ij \rangle\rangle} c_i^\dagger \sigma \cdot (\mathbf{d}_{ij} \times \mathbf{d}_{ik}) c_j + iV_R \sum_{\langle ij \rangle} c_i^\dagger \hat{z} \cdot (\sigma \times \mathbf{d}_{ij}) c_j + \sum_i w_i c_i^\dagger c_i, \quad (1)$$

where $c_i^\dagger = (c_{i\uparrow}^\dagger, c_{i\downarrow}^\dagger)$ denotes electron creation operators for spin up and spin down, and σ is the Pauli matrix. The first term is the nearest-neighbor (NN) hopping, and the second term is the intrinsic spin-orbital coupling between the next-nearest-neighbor (NNN) sites i, j with k being their shared NN site, where $\mathbf{d}_{ik} = \mathbf{R}_i - \mathbf{R}_k$ is the displacement vector. The third term stands for the Rashba spin-orbital coupling, and the last term is an on-site random disorder with strength uniformly distributed within $|w_i| \leq W/2$.

We first discuss the physics of this two-component Haldane model without the Rashba spin-orbital coupling ($V_R = 0$). In this case, each spin component is subject to the complex NNN hoppings as illustrated in Fig. 1(a), where the hoppings are complex conjugate of each other for the two spin components. Therefore, the energy spectrum is gapped with Chern number $C^{up} = 1$ ($C^{down} = -1$) for the lower band of spin up (spin down), leading to the IQHE for each spin component. The Chern number of a band can be obtained as (Thouless et al., 1982):

$$C = \frac{i}{2\pi} \int d^2k \left[\left\langle \frac{\partial u_k}{\partial k_x} \middle| \frac{\partial u_k}{\partial k_y} \right\rangle - \left\langle \frac{\partial u_k}{\partial k_y} \middle| \frac{\partial u_k}{\partial k_x} \right\rangle \right], \quad (2)$$

where u_k is the single-particle wave function of an energy band at a given momentum $\mathbf{k} = (k_x, k_y)$. The IQHE can be characterized by the topological Chern number associated with each band, and the Hall conductance of the system is proportional to the total Chern number of all the occupied bands (Thouless et al., 1982). If we consider the Fermi energy $E_F = 0$, there are two occupied bands with opposite spins and opposite Chern numbers, which give rise to the vanished total Hall conductance $\sigma_H = 0$. However, following the simple version of spin Chern number $C^s = C^{up} - C^{down} = 2$, the spin Hall conductance is nonzero, $\sigma_H^s = e/(2\pi)$. For the two bands with nonzero Chern numbers, there are corresponding gapless edge modes carrying opposite currents and opposite spins.

In the presence of the Rashba coupling ($V_R \neq 0$), each eigenstate has mixed spins. We can explicitly compute the spin polarization $P_m^z = \frac{\hbar}{2} \langle m | \sum_i c_i^\dagger \sigma^z c_i | m \rangle$ along the $\hat{z}$ -direction with $|m\rangle$ as the m -th single-particle eigenstate. Spin polarizations along the $\hat{x}$ - and $\hat{y}$ -directions are found much smaller. Interestingly, all the eigenstates form Kramers degenerate pairs and each pair carry zero total spin due to time-reversal symmetry before we insert flux into the system. However, if a small flux is inserted into the system (or using the twisted boundary condition), a nonzero spin polarization will be quickly developed for each edge state (Sheng et al., 2006). The spin polarization is finite only for the edge states within the bulk energy gap and insensitive to disorder configuration and sample size, which clearly demonstrates that the current-carrying edge states have finite spin polarization and thus lead to the QSHE.

(a) The Haldane model has the nearest-neighbor hopping t_1 and next-nearest-neighbor hopping t_2 . t_2 is complex and denotes the charge hopping along the arrow direction. (b) Illustration of the chiral edge currents along the opposite directions in the open boundaries.

Z_2 characterization of topological insulators

The nonzero Z_2 topological index characterizes the time-reversal invariant topological insulators with symmetry protected edge transport (Kane and Mele, 2005a; Andrei Bernevig et al., 2006; Liang and Kane, 2006; Roy, 2009; Moore and Balents, 2007). The Z_2 topological insulator has an odd number of Kramers pairs of gapless edge modes. In the original work of Kane and Mele (2005a), the Z_2 invariant is obtained based on the K -theory by calculating the Pfaffian of the matrix of time reversal operator. Later, other methods are introduced, including using the non-Abelian Berry connection (Fukui and Fujiwara, 2009; Rui et al., 2011), the Berry curvature and Chern number in the effective Brillouin zone (EBZ) (Liang and Kane, 2006; Roy, 2009; Moore and Balents, 2007), and spin Chern number (Sheng et al., 2006; Prodan, 2009, 2011). The spin Chern number for a time-reversal invariant system with a projected spin gap can be connected to the Z_2 invariant through the relation $Z_2 = \text{mod}(C^s/2, 2)$.

Time-reversal symmetry connects the quantum states in the EBZ with the states in other half Brillouin zone. By mapping the EBZ to the space of the Bloch Hamiltonian, a Chern number associated with the EBZ can be defined, which classifies the energy band structure into two topological classes, namely a nontrivial (trivial) topological class characterized by an odd (even) Chern number as demonstrated by Moore and Balents (2007). The obtained topological invariants in 2D are multiple copies of the Z_2 invariant, and there are four such invariants per band pair in three dimensions, which characterize three-dimensional topological insulators (Moore and Balents, 2007; Liang et al., 2007; Fukui and Hatsugai, 2007).

Fu and Kane defined a Z_2 pump characterized by a Z_2 topological invariant (Liang and Kane, 2006). For an isolated system, a single cycle of the pumping process can effectively pump spins between the open edges even when the spin of the system is not conserved due to spin-orbital interaction. When the system is coupled to leads, it is demonstrated that the Z_2 pump works as a spin pump, which transmits spins at a finite rate and leads to a robust QSHE.

Many-body Chern number matrix

To generalize the Chern number definition of an energy band to multi-component systems, we introduce many-body Chern number (Sheng et al., 2003a), which can effectively characterize the bulk topological nature of quantum systems with spin coupling and electron-electron interaction. Because electrons can have both charge and spin responses, we can consider spin-dependent boundary phases to obtain the generalized topological Chern number matrix (Sheng et al., 2006). We start from applying a boundary condition for a two-dimensional many-body wave-function: $\Phi(\dots, \mathbf{r}_{i_x} + \mathbf{L}_{j_x}, \dots) = e^{i\theta_j^x} \Phi(\dots, \mathbf{r}_{i_x}, \dots)$, where $j = x$ or y , the system length vectors are $\mathbf{L}_x, \mathbf{L}_y$, and $\alpha = \uparrow$ and $\downarrow$ denotes spin index. Through a unitary transformation $\Psi = \exp \left[-i \sum_{\alpha} \sum_{i_x} \left(\frac{\theta_x^{\alpha}}{L_x} x_{i_x} + \frac{\theta_y^{\alpha}}{L_y} y_{i_x} \right) \right] \Phi$, where the summation runs over all electrons, Ψ becomes periodic on a torus. One can now define the topological Chern numbers as:

$$C^{\alpha, \beta} = \frac{i}{2\pi} \int \int d\theta_x^{\alpha} d\theta_y^{\beta} \left[\left\langle \frac{\partial \Psi}{\partial \theta_x^{\alpha}} \middle| \frac{\partial \Psi}{\partial \theta_y^{\beta}} \right\rangle - \left\langle \frac{\partial \Psi}{\partial \theta_y^{\beta}} \middle| \frac{\partial \Psi}{\partial \theta_x^{\alpha}} \right\rangle \right], \quad (3)$$

where the area integration is over a unit cell $0 \leq \theta_x^{\alpha}, \theta_y^{\beta} \leq 2\pi$. With $\alpha, \beta = \uparrow, \downarrow$, $C^{\alpha, \beta}$ form a 2×2 Chern number matrix. Each element of the Chern number matrix is exactly quantized as an integer for a gapped insulating state following the argument of Thouless et al. (1982).

We calculate the topological Chern number matrix numerically by dividing the unit cell of the boundary phases into N_{mesh} mesh points such that the integration in Eq. (3) is replaced by the sum of the solid angle Ω_j : $C^s = \sum_j \frac{\Omega_j}{2\pi}$. Here, $\Omega_j = \arg \Pi_i \langle \Psi_{ji} | \Psi_{ji+1} \rangle$ where $i = 1-4$ (with $j_5 \equiv j_1$) denote the four parameter points in the boundary phase space around the j -th square of mesh patches. The Chern number matrix obtained by this way is well converged and insensitive to mesh sizes.

In the case without Rashba coupling ($V_R = 0$), only the diagonal matrix elements are nonzero: $C^{\alpha, \alpha} = \pm 1$ (for positive V_{SO}) with $\alpha = 1$ and 2 representing spin up and down, respectively. This matrix describes the IQHE in decoupled subsystems. The total charge Chern number $C^c \equiv \sum_{\alpha, \beta} C^{\alpha, \beta}$ (corresponding to the total charge Hall conductance) cancels out, while the total spin-related Chern number is quantized to $C^s \equiv \sum_{\alpha, \beta} \alpha C^{\alpha, \beta} = 2$, which represents the spin Hall response when a common electric field for both spin components is imposed along the $\hat{y}$ direction. In this spin decoupled limit, the quantized spin Chern number C^s is associated with the spin Hall conductance $\sigma_{H}^s = C^s = 2$ in units of $\frac{e}{4\pi}$.

Now we turn on the Rashba coupling and discuss how to numerically determine C^s . This can be done by calculating each $C^{\alpha, \beta}$ first as discussed above. One can also carry out the integration in Eq. (3) for opposite boundary condition along the $\hat{x}$ direction (spin twist $\theta_x^{\uparrow} = -\theta_x^{\downarrow} = \theta_x$) and common one along the $\hat{y}$ direction ($\theta_y^{\uparrow} = \theta_y^{\downarrow} = \theta_y$) to directly obtain C^s . We choose the latter method in the following. One finds that C^s always remains quantized at $C^s = 2$ before the band gap collapses. In Fig. 2(a), we show the energy spectrum for $V_R = 0.1 t$ and $V_{SO} = 0.3 t$, where a gap appears between the two lower bands and the two upper bands. With Rashba coupling, the two lower bands are spin entangled. The relation between the QSHE, spin pumping through edge states and spin Chern number has been addressed by our previous work and the work by Prodan (2009, 2011). One can obtain the spin spectrum for the occupied states by defining the matrix $M(s_z) = P_- \sigma_z P_-$ with P_- being the projection operator to the occupied eigenstates. This allows us to analyze the spin spectrum for the occupied states by diagonalizing the matrix $M(s_z)$. Because Hamiltonian is block-diagonalized for pure system without considering disorder scattering, we can do the similar block diagonalization for $M(s_z)$. The obtained spin spectrum is shown in Fig. 2(b). Interestingly, the spin information of the eigenstates is revealed by the

Fig. 2 (a) Energy spectrum for the two-component Haldane model with intrinsic spin-orbital coupling. (b) The spin eigenvalues for the projected spin S_z operator, where a spin gap is identified between the spin states with different polarizations. These states with near opposite spin polarizations also have opposite Chern numbers. (c) The helical edge states for such a system with nonzero spin Chern number is illustrated.

spin spectrum, which separates into two disentangled bands, with near quantized spin quantum numbers $\sigma_z \approx \pm 1$ (here we use Pauli matrix for spin operator). Physically, these two projected bands carry opposite Chern numbers and near oppositely polarized spins, which contribute to the quantized spin Chern number. The exactly quantized spin Chern number is protected simultaneously by the energy spectrum gap and project spin spectrum gap. The helical edge states corresponding to the nonzero spin Chern number is illustrated in Fig. 2(c), which is responsible for the nearly quantized spin Hall conductance (Sheng et al., 2006). The gapless feature is protected by time-reversal symmetry or nonzero Z_2 topological invariant. Such a topologically nontrivial phase also survives for very small V_{SO} , so long as V_R is not much larger than V_{SO} . With the increase of the Rashba coupling, at a larger $V_R = 0.33 t$ with a fixed $V_{SO} = 0.1 t$, the energy gap is about to collapse, and spin gap also closes around a similar critical point, signaling a topological transition from topological insulator to a metallic state (Sheng et al., 2006).

The fractional quantum spin Hall effect

What is the effect of interaction in topological insulators? It has been shown that topological insulators are also robust against not too strong interaction (Cenke and Moore, 2006; Lee and Ryu, 2008; Rachel, 2018). Interestingly, for strongly interacted systems, there may be a new class of topological insulators, characterized by counterpropagating edge states and fractionalized spin Hall effect as suggested by theoretical studies (Levin and Stern, 2009; Swingle et al., 2011; Neupert et al., 2011; Chen and Yang, 2012; Ghaemi et al., 2012). The basic physical picture is simple, as fractionalized quantum phases can emerge when electrons fractionally fill the effective Landau levels generated by spin-orbital couplings. Because interaction effect is competing with kinetic energy, the topological insulator with relatively flat energy band is a desired condition for hosting fractional quantum spin Hall effect (FQSHE).

We first consider a simple model of two-component system with electrons of the opposite spins or pseudospins (valley or layer degrees of freedom) subjected to spin-dependent magnetic fields opposite to each other (Ghaemi et al., 2012), with a non-interacting Hamiltonian

$$H_0 = \frac{1}{2m} (\mathbf{p} - \sigma_z \frac{e\mathbf{A}}{c})^2. \quad (4)$$

Due to the applied magnetic fields, Landau levels are realized for each spin species. We can consider the effects of two-particle interactions $H_{int} = V(\mathbf{r}_1, \mathbf{r}_2)$, which can be projected into the lowest Landau levels or partially occupied excited Landau levels. In the absence of any coupling between two spin degrees of freedom but only interactions within each spin component, uncoupled fractional quantum Hall states are realized for each spin component, which will contribute to a FQSHE. However, this is a trivial case as it belongs to the same universality class as the FQHE. Our goal is to discuss the nontrivial FQSHE in which two spins are effectively coupled by spin-orbital coupling or Coulomb interaction. To proceed, we project the Hamiltonian into the lowest Landau level for each spin. The inter-spin Coulomb term is different from the intra-spin interaction as it couples the two components with opposite vector potentials as well as different center of cyclotron orbits.

The numerical results are presented in Fig. 3 to illustrate the ground state degeneracy for an electron system with total filling number $2/3$ (each layer is at $1/3$ filling). We show the energy spectrum as a function of layer separation d and assume that the inter-layer Coulomb interaction decays with the layer separation and there is no tunneling (Sheng et al., 2003a). The lowest level has nine near-degenerate states (each level shown here has a threefold degeneracy) at large d side, which is well separated from the excited levels by an energy gap. The gap closes near a finite layer separation $d_c \sim 1.2 l$ (l is the magnetic length), where a transition to a metallic state takes place. Similar physics was first identified by Chen and Yang (Chen and Yang, 2012).

What is the nature of the quantum phase at large d side? When two spin components are only coupled by the Coulomb interaction, the spin (or pseudospin) S_z is conserved. The Chern number matrix can fully characterize the topological properties of the state (Sheng et al., 2003a,b). The charge Chern number is zero because of time-reversal symmetry. The combined Chern number which has the one-to-one relation to the quantum spin Hall effect is the spin Chern number, $C^s = \sum_{\alpha, \beta}$

Fig. 3 The low-energy spectrum of the $1/3 + 1/3$ system as a function of the layer separation d with zero Rashba coupling. The excitation gap is shown to be robust at large d side, separating the ground state manifold (only three levels in the ground state manifold are shown, each representing three degenerating levels) from higher excited states until $d_c \sim 1.2$ l (l is magnetic length). At $d > 1.2$ l side, the FQSHE remains to be robust characterized by a quantized spin Chern number $C^s = \frac{2}{3}$ and fractional quantized spin Hall conductance $\frac{2}{3} e/4\pi$ for this spin conserved system.

$\alpha C^{\alpha\beta} = C^{1,1} + C^{1,2} - C^{2,1} - C^{2,2}$. Physically, the spin Chern number represents a spin-Hall response of the system to the common electric field. For a pure system without disorder, we find that $C^s = 2/3$ for each energy level in the ground state manifold (Ghaemi et al., 2012). This is a nontrivial result since each of the many-body state has a spin lying in the $x - y$ plane with total spin $S_z = 0$. In other words, this new quantum phase belongs to a new class of fractional topological insulator (Levin and Stern, 2009) similar to its integer partner which has the Z_2 invariant (Kane and Mele, 2005a).

How robust is the FQSHE state? We first discuss the effect of the disorder. With the presence of disorder scattering, the spin Chern number carried by each eigenstate immediately becomes integer quantized similar to the one in the $1/3$ FQHE (Sheng et al., 2003b). Remarkably, the total spin Chern number of each three states are conserved, which is quantized at $C_{tot}^s = \sum_{i=1}^3 C_i^s = 2$ just like in the pure limit. Thus the FQSHE remains robust as the spin Chern number averaged for each state remains to be $2/3$. Furthermore, we address the issue of Rashba coupling. With a finite Rashba coupling, the spins are free to flip, which induces an effective tunneling between two layers (or two spin components). The low-energy spectrum and the spin Chern number quantization will remain robust for small Rashba coupling.

The strained honeycomb lattices are promising platforms to realize fractional topological phase in the absence of any magnetic field. The strain-induced pseudomagnetic fields are oppositely oriented in the two valleys which are readily hosting FQHE in each valley. However, for realistic Coulomb interactions, the coupling between two valleys are too strong for inducing FQSHE. Motivated by artificial graphene systems, Ghaemi et al. considered tuning the short-range part of interactions and showed that exotic valley fractional topological insulator can be induced through attractive neighboring interactions in addition to the repulsive Coulomb interactions.

Fractionalized spin Hall transport in frustrated spin systems

Another interesting direction for observing topological phase is two-dimensional frustrated spin systems, where transverse spin transport may emerge when time-reversal symmetry is spontaneously broken. The observed state is known as the chiral spin liquid (CSL) with gapless chiral edge modes, which is an analog of the bosonic FQHE. The CSL was first proposed in 1987 (Kalmeyer and Laughlin, 1987; Wen et al., 1989), and in recent years the Kalmeyer-Laughlin CSL corresponding to the $\nu = 1/2$ FQHE state has been identified in different frustrated spin systems (He et al., 2014; Gong et al., 2014; Bauer et al., 2014; Kumar et al., 2015).

The chiral edge states in CSL can be probed by spin transport and associated Chern number. As an example, we consider a spin- $1/2$ system on a cylinder geometry. If a flux is inserted in the cylinder, the spin flip terms along the circumference direction have an additional phase. By increasing the flux adiabatically, spin transport can be detected by measuring the accumulated spin on the open edges. For the Kalmeyer-Laughlin CSL, a quantized Chern number $1/2$ will be obtained with the flux increasing from zero to 2π , corresponding to a pumped fractionalized spinon with spin- $1/2$.

Conclusion

The topological insulator is one of great discoveries in recent 20 years. There are many experimental realizations in real materials for rich varieties of topological phases in two and three dimensional systems (Hasan and Kane, 2010). The interplay between the nontrivial band topology and interaction remains to be one of the most challenging issues to be fully understood, which will also bring more exciting discoveries including fractional quantum spin Hall effect and bosonic topological insulators (Vishwanath and Senthil, 2013), and topological superconductivity in complex materials (Liang and Kane, 2008; Qi and Zhang, 2011).

Abstract

In this Chapter, we give a brief review of the state of the art of theoretical and experimental studies of synthetic magnetic fields and quantum Hall effects in ultracold atomic gases. We focus on integer, spin, and fractional Hall effects, indicate connections to topological matter, and discuss prospects for the realization of full-edged gauge field theories where the synthetic magnetic field has its own dynamics. The advantages of these systems over traditional electronic systems are highlighted. Finally, interdisciplinary comparisons with other synthetic matter platforms based on photonic and trapped-ion systems are drawn. We hope this chapter to illustrate the exciting progress that the field has experienced in recent years.

Key points

This chapter aims to

- illustrate how synthetic magnetic fields can effectively be generated in neutral matter;
- highlight breakthroughs in realizing integer and spin quantum Hall effect;
- showcase steps toward strongly interacting systems displaying the fractional quantum Hall effect;
- illustrate some of the rich physics that can be achieved when the atoms act back on the synthetic gauge fields;
- emphasize the fascinating progress of the field and the outstanding main challenges.

Introduction

The discovery of the quantum Hall (QH) effects in two-dimensional electron gases subject to a strong magnetic field has revolutionized our view of quantum condensed-matter physics and has opened a new field of research at the crossroad with quantum information and topology (Tong, 2016). While usual phase transitions such as ferromagnetism or even Bose–Einstein condensation are described within the Landau–Ginzburg theory by the onset of a macroscopic order parameter, topological states of matter cannot be revealed by the measurement of any local observable and instead are characterized by subtle quantum correlations between the constituent particles (Kitaev and Preskill, 2006; Levin and Wen, 2006; Wen, 1995, 2013). The most direct signature of integer and fractional quantum Hall states is the quantized value of the transverse conductivity in units of e^2/h . Besides opening windows into novel physical phenomena of fundamental interest, such states have been also anticipated for practical applications in quantum information processing, e.g., as a promising platform to transmit quantum information and protect it from decoherence (Nayak et al., 2008).

Beyond the traditional observation of quantum Hall effects in electron gases in solid-state devices, a strong activity is presently being devoted to synthetic quantum matter systems (Ozawa and Price, 2019) such as gases of ultracold atoms (Cooper, 2008; Pitaevskii and Stringari, 2016), spin and phonon systems realized in trapped ions (Bermudez et al., 2011; Geier et al., 2021b; Manovitz et al., 2020; Nigg et al., 2014), or fluids of strongly interacting photons in nonlinear topological photonics devices (Carusotto and Ciuti, 2013; Carusotto et al., 2020). In all these systems, the charge neutrality of the constituent particles requires introducing a so-called synthetic magnetic field in order to observe QH physics (Dalibard, 2016; Dalibard et al., 2011; Goldman et al., 2014); at the same time, such systems allow for a broader range of techniques for the manipulation and diagnostics well

beyond the standard transport and optical probes of solid state systems (Yoshioka, 2002), which opens exciting new perspectives to experimental studies. While a number of phenomena related to the integer quantum Hall (IQH) effect have been observed in the last years for non-interacting particles in suitably designed band structures for either atoms or photons, fractional quantum Hall (FQH) effects require strong interactions among particles and low temperatures, and are still a subject of intense work.

In what follows, we give a timely account of the state of the art of experimental and theoretical research toward the realization of FQH liquids of ultracold atoms. We also discuss relatively novel directions, where the magnetic vector potential acquires its own dynamics, leading to interesting backaction effects of matter particles onto the synthetic magnetic field and even to full-edged gauge theories reminiscent of quantum electrodynamics. This chapter thus complements other reviews on synthetic gauge fields (Dalibard, 2016; Dalibard et al., 2011; Goldman et al., 2014), on rotating atomic clouds (Cooper, 2008), and on topological effects in synthetic quantum matter (Cooper et al., 2019; Ozawa and Price, 2019; Zhang et al., 2018). While the main focus of our discussion here will be on ultracold atoms, connections to other promising platforms such as trapped ions or photonic devices will also be drawn.

This review chapter is organized as follows. In Section “Synthetic magnetic fields,” we recapitulate approaches to imbuing ultracold atomic gases with synthetic magnetic fields, a key prerequisite for observing QH physics. Sections “Integer quantum Hall effect” and “Fractional quantum hall effect in cold atoms” discuss recent advances in cold atom systems in observing the IQH and FQH, respectively. In Section “Dynamical vector potentials,” we highlight some recent developments in inducing backaction of the matter system onto the synthetic magnetic field, leading to the generation of dynamical Peierls phases and even to pioneering steps in the creation of lattice gauge theories. Section “Conclusion” contains our conclusions and some further outlooks.

Synthetic magnetic fields

The motion of quantum mechanical particles of mass m and charge q in a classical background magnetic field is described via the minimal coupling Hamiltonian

$$H_{\text{kin}} = \frac{(\mathbf{P} - \frac{q}{c}\mathbf{A})^2}{2m} \quad (1)$$

in terms of the vector potential $\mathbf{A}(\mathbf{r})$, related to the magnetic field by $\mathbf{B} = \text{rot}\mathbf{A}$. In a discrete, spatially-periodic lattice geometry, this Hamiltonian can be reformulated in terms of a non-trivial hopping phase in the tight-binding Hamiltonian,

$$H_{\text{kin}} = -J \sum_{\langle i, j \rangle} \psi_i^\dagger U_{ij} \psi_j, \quad (2)$$

where J is the bare hopping amplitude, $\psi_i^\dagger$ and ψ_i are fermionic or bosonic creation and annihilation operators at lattice site i , respectively, and $U_{ij} = \exp\left(i\frac{q}{c}\int_{\mathbf{r}_i}^{\mathbf{r}_j} \text{dr} \cdot \mathbf{A}(\mathbf{r})\right)$ is the Peierls phase, corresponding to the Aharonov–Bohm phase accumulated by the particle when moving from site i to site j . Starting from these formulations, it is straightforward to derive the celebrated features of quantum mechanical motion in magnetic fields, such as cyclotron motion and Landau levels (Girvin, 1999; Tong, 2016).

Since atoms are charge neutral ($q = 0$), it is impossible to observe this physics using standard magnetic fields, whose effect on atoms typically reduces to Zeeman shifts of the internal levels. More subtle manipulations are therefore necessary to generate effective vector potentials affecting the orbital atomic motion along the lines of Eqs. (1) or (2). Over the years, a number of strategies to generate such *synthetic magnetic fields* have been developed. Here, we will briefly review the most promising and/or physically transparent ones (Dalibard, 2016; Dalibard et al., 2011; Goldman et al., 2014). As the basic object realized in the experiments is typically the vector potential, gauge-invariance of the framework raises interesting subtleties in the conceptual analysis of the experiments (LeBlanc et al., 2015). Though synthetic gauge fields give rise also to other intriguing effects, e.g., supersolid behavior (Geier et al., 2021a; Li et al., 2017; Putra et al., 2020), our attention in this review will be focused on the family of integer and fractional Quantum Hall effects.

Historically, the first strategy was based on the mathematical analogy between the Coriolis force $\mathbf{F} = \mathbf{v} \times \boldsymbol{\Omega}$ in a rotating frame and the Lorentz force $\mathbf{F} = q\frac{\mathbf{v}}{c} \times \mathbf{B}$ in a magnetic field. By putting the atom trap into mechanical rotation around some axis, the atomic cloud gets to equilibrate in a rotating frame where the angular speed plays the role of the magnetic field. Over the years, this approach has led to pioneering advances for weakly interacting Bose–Einstein condensates, such as the observation of periodic arrays of quantized vortices (Abo-Shaeer et al., 2001; Bretin et al., 2004; Schweikhard et al., 2004) resembling the Abrikosov vortex arrays generated by magnetic fields in type-II superconductors.

A conceptually different approach to generate a synthetic magnetic field is based on the Berry phase that moving atoms experience when they are dressed by a suitable combination of optical, micro- and radio-wave, and static electromagnetic fields (Dum and Olshanii, 1996; Juzeliunas and Öhberg, 2004; Ruseckas et al., 2005): in this framework, the roles of the vector potential and of the magnetic field are played by the Berry connection and the Berry curvature, respectively. Remarkable outcomes of this approach include the nucleation of quantized vortices under the effect of strong enough synthetic fields (Lin et al., 2009), as highlighted in Fig. 1.

Discrete, spatially periodic geometries realized by imposing optical lattice potentials offer additional tools to generate synthetic magnetic fields via non-trivial hopping phases. Complex hopping phases induced by inter-site Raman processes were first proposed in Jaksch and Zoller (2003), Mueller (2004), Osterloh et al. (2005), Sorensen et al. (2005) and then implemented to realize, e.g., an atomic Harper–Hofstadter model (Aidelsburger et al., 2013; Miyake et al., 2013).

Copyright Springer Nature Ltd. 2009.

Alternatively, non-trivial band geometries and topologies have been realized in a Floquet framework based on periodic shaking or time-modulation of the lattice potential (Bukov et al., 2015; Eckardt and Anisimovas, 2015). By suitably choosing the shaking protocol, e.g., such that the periodic shaking function explicitly breaks time-reversal symmetry, one can obtain—in a time-averaged or stroboscopic Floquet description—an effective Hamiltonian that has a non-trivial Peierls phase (Goldman and Dalibard, 2014; Hauke et al., 2012; Kitagawa et al., 2010, 2011; Kolovsky, 2011; Oka and Aoki, 2009; Struck et al., 2012). This approach has led to the realization of the Haldane (Jotzu et al., 2014) and the Harper–Hofstadter model (Aidelsburger et al., 2015).

An exciting new frontier of these investigations is to combine the internal and orbital dynamics of atoms into a single geometric entity so to realize configurations with a larger number of effective spatial dimensions than the usual three spatial ones (Celi et al., 2014), where to observe new magnetic and topological effects that are peculiar of high dimensionalities (Price et al., 2015). Pioneering steps in the direction of realizing such *synthetic dimensions* were reported in the experiments of Mancini et al. (2015), Stuhl et al. (2015).

Integer quantum Hall effect

In electronics, the main signature of the Integer Quantum Hall (IQH) effect consists in a quantized value of the transverse conductance to integer multiples of e^2/h whenever electrons completely fill an integer number of Landau levels (Tong, 2016). Soon after the discovery of the IQH, it was realized that the quantized conductance can be related to integer-valued topological invariants characterizing the geometry of the electronic bands (Thouless et al., 1982). In a modern understanding, IQH systems are then interpreted as an example of the wider class of topological insulators, where the bulk-boundary correspondence translates topological properties of the bands of the insulating bulk into chiral currents around the edges of the sample (Hasan and Kane, 2010), see Fig. 2(a). Since these features are related to integer-valued topological invariants, they are resilient against disorder and similar types of small perturbations.

Based on such insights, the IQH effect could be studied in a number of atomic systems: even though conductivity experiments analogous to electronic ones are not naturally performed in atomic systems, many other observables are available to obtain an even deeper information on the properties of this state of matter.

IQH in cold atoms

Anomalous Hall effects were first predicted in the atomic context in Dudarev et al. (2004) and experimentally observed in honeycomb-like lattices in Jotzu et al. (2014) as a lateral displacement of the atoms whenever their k -space distribution is pushed

Fig. 2 (a) Integer Quantum Hall effect. A synthetic magnetic field pierces a cloud of ultracold neutral atoms, induced, e.g., by trap rotation, Berry phase imprinting, or lattice shaking. Within the bulk, this leads to cyclotron motion. The corresponding skipping orbits at the boundary add up to a chiral edge current, which is protected by the topology of the sample. (b) Spin Hall effect. Two (pseudo)-spin states (e.g., two atomic hyperfine states) see an opposite synthetic magnetic field. As a result, the system has vanishing net charge transport, but the presence of helical edge states results in a topologically protected spin current around its boundaries.

across a finite-Berry-curvature region. A quantized displacement analogous to the IQH was then observed for an atomic cloud uniformly filling a band (Aidelsburger et al., 2015). A precursor of this was the measurement of the Zak phase characterizing topological Bloch bands in a one-dimensional optical lattice (Atala et al., 2013).

While chiral edge states have been the major workhorse to characterize topological photonic systems (Ozawa et al., 2019), a relatively limited number of experiments have investigated edge currents in atomic systems. On the one hand, this is due to the difficulty of directly measuring currents in cold-atom systems, though significant theoretical and experimental advances have been achieved in recent years (Brown et al., 2019; Geier et al., 2021b; Hauke et al., 2014; Jepsen et al., 2020; Keßler and Marquardt, 2014; Krinner et al., 2015; Laflamme et al., 2017; Nichols et al., 2019; Scherg et al., 2018). On the other hand, an obstacle is the absence of sharp boundaries in standard, harmonically trapped atomic clouds. Also for this reason, the remarkable studies of edge transport in Mancini et al. (2015), Stuhl et al. (2015) illustrated in Fig. 3 made use of a synthetic dimension set-up combining a spatially one-dimensional lattice with an additional dimension formed by the internal spin degrees.

A great advantage of atomic systems is the possibility of combining macroscopic transport measurements with a direct microscopic insight into the quantum many-body wavefunction (Gebert et al., 2020). In the IQH context, a remarkable example in this direction was the experimental tomography of the Berry phase (Fläschner et al., 2016; Hauke et al., 2014), with follow-ups such as the identification of dynamical topological invariants in the time evolution of an atomic system (Tarnowski et al., 2019).

Extensions

An important extension of the IQH effect is obtained when a spin degree of freedom of the particles is included, $\sigma = \uparrow, \downarrow$, such that Eq. (2) becomes $H_{\text{kin}} = -J \sum_{\langle ij \rangle} \sum_{\sigma} \psi_{i,\sigma}^{\dagger} U_{i,j}^{\sigma} \psi_{j,\sigma}$. In the so-called spin-Hall effect (Hasan and Kane, 2010), particles with different spin orientations see opposite magnetic fields, $(U_{i,j}^{\uparrow})^{\dagger} = U_{i,j}^{\downarrow}$ and time-reversal symmetry is restored. The result is a system without any net charge current but chiral spin edge currents that run around the sample in opposite directions, see Fig. 2(b). Pioneering proposals have been based on extending schemes for light-induced vector potentials to several hyperfine levels (Zhu et al., 2006) and on state-dependent, slowly time-varying magnetic potentials engineered in an atom chip on a micron scale (Goldman et al., 2010). The spin Hall effect has been observed in free space, where spin-dependent Lorentz forces have been measured using a spatially inhomogeneous spin-orbit coupling field (Beeler et al., 2013), as well as in an optical lattice using laser-assisted tunneling induced in a tilted optical lattice via periodic driving (Aidelsburger et al., 2013).

This physics can be generalized even further by replacing the spin-dependent Peierls phase by a matrix, $H_{\text{kin}} = -J \sum_{\langle ij \rangle} \sum_{\sigma, \sigma'} \psi_{i,\sigma}^{\dagger} U_{i,j}^{\sigma, \sigma'} \psi_{j, \sigma'}$, where $U_{i,j}^{\sigma, \sigma'}$ mixes the different spin states during hopping. Genuinely non-Abelian effects occur if the product of the $U_{i,j}^{\sigma, \sigma'}$ around a closed path (the non-Abelian Wegner–Wilson loop) does not reduce to a simple phase factor $e^{i\phi} \mathbb{1}$. Such a situation can be obtained through periodically shaken optical superlattices where an internal degree of freedom of the atoms plays the role of the (pseudo-) spin (Hauke et al., 2012). As a striking consequence of the non-Abelian Hall effect, novel fractal features have been predicted to appear in the phase diagram (Bermudez et al., 2010; Goldman et al., 2009).

Another exciting direction of research concerns the extension of IQH effects to higher-dimensional, $4 + 1$ geometries as first proposed in Price et al. (2015) using the concept of synthetic dimensions mentioned above. Pioneering experimental evidence of

Fig. 3 Experimental observation of edge-cyclotron orbits in a synthetic three-leg ladder system based on a spatial x dimension and a synthetic dimension encoded in the atomic spin. From Mancini, M, Pagano, G, Cappellini, G, Livi, L, Rider, M, Catani, J, Sias, C, Zoller, P, Inguscio, M, Dalmonte, M et al. (2015) Observation of chiral edge states with neutral fermions in synthetic hall ribbons. *Science* 349(6255): 1510–1513. Reprinted with permission from AAAS.

the role of higher-dimensional topological invariants in the atomic transport properties under crossed synthetic-electric and magnetic fields in 4-dimensional models was reported in [Lohse et al. \(2018\)](#).

Fractional quantum hall effect in cold atoms

In the previous section, we have seen the intriguing effects that appear in the presence of completely occupied Landau levels or topological bands, but where interactions play at most a subdominant role. Even more subtle physics occurs when the macroscopic degeneracy of partially filled Landau levels is lifted by strong inter-particle interactions and the lowest energy state acquires a non-trivial topology for the many-body wavefunction ([Kitaev and Preskill, 2006](#); [Levin and Wen, 2006](#); [Wen, 1995, 2013](#)).

One of the most celebrated examples of such topological many-body phases of matter is the so-called fractional quantum Hall (FQH) effect, first detected in two-dimensional electron gases under strong magnetic fields as a precise quantization of the transverse conductivity at rational values proportional to the electron filling, i.e., the number of electrons per unit magnetic flux piercing the system ([Girvin, 1999](#); [Tong, 2016](#); [Yoshioka, 2002](#)). As even more intriguing signatures of the many-body topology of the FQH state, excitations with a fractional charge and fractional statistics have been anticipated for these systems, the so-called *anyons* ([Stern, 2008](#)). While fractionally charged edge excitations have been observed in shot-noise measurements ([De-Picciotto et al., 1998](#); [Saminadayar et al., 1997](#)), the observation of fractional statistical properties interpolating between bosonic and fermionic behaviors is still the subject of intense experimental work ([Bartolomei et al., 2020](#); [Nakamura et al., 2020](#)).

First steps towards the realization of FQH fluids using ultracold atomic clouds were made by pushing the rotation frequency toward the trapping frequency, so that the atomic cloud expands in space under the effect of the centrifugal potential and reaches the required magnetic flux per particle values. For sufficiently low temperatures, it is then predicted to enter a FQH state ([Cooper, 2008](#)). In spite of early concerns about heating due to spurious asymmetries of the trap potential and the need for a fine tuning of the rotation speed, remarkable advances on condensates in rotating traps have been recently reported ([Fletcher et al., 2021](#); [Mukherjee et al., 2022](#)). Besides these works on a mean-field-interacting dynamics, hints of correlated FQH physics have been reported in small atomic clusters trapped at the rotating minima of a temporally modulated optical lattice potential ([Gemelke et al., 2010](#)). A different strategy to realize a strongly interacting Harper–Hofstadter lattice using a combination of optical lattice potentials and Raman transitions was adopted in [Tai et al. \(2017\)](#) and led to the observation of a correlated two-particle dynamics, a precursor of fractional quantum Hall effects, see [Fig. 4](#). In the meanwhile, an intense theoretical activity has been devoted to the study of alternative protocols to realize FQH states using, e.g., adiabatic ramps along suitably designed paths in parameter space ([Popp et al., 2004](#); [Sorensen et al., 2005](#)) or sequences of adiabatic flux insertion and hole replenishing ([Grusdt et al., 2014](#)).

The main advantage of FQH fluids of ultracold atoms over solid-state systems is the much wider variety of manipulation and diagnostics tools compared to the transport and optical probes traditionally available for electronic systems. While waiting for macroscopic FQH clouds to be experimentally realized, theoretical proposals to investigate their intriguing properties include interferometric techniques ([Grusdt et al., 2016](#); [Paredes et al., 2001](#)), quasi-hole dynamics in response to external potentials ([Grass et al., 2012](#)), microscopic imaging of the density profile of a quasi-hole ([Macaluso et al., 2020](#)), quantum mechanics of anyonic molecules formed by an impurity bound to a FQH quasi-hole ([Baldelli et al., 2021](#); [De Las Heras et al., 2020](#); [Zhang et al., 2014](#); [Lundholm and Rougerie, 2016](#); [Yakaboylu et al., 2020](#)), the center of mass motion of the cloud ([Repellin et al., 2020](#)), its circular-dichroic response to circular excitations in the bulk ([Repellin and Goldman, 2019](#)), or the linear and nonlinear response of the edge modes ([Nardin and Carusotto, 2022](#)).

Together with direct measurements of the entanglement entropy ([Jiang et al., 2012](#); [Li and Haldane, 2008](#)) as experimentally pioneered in [Islam et al. \(2015\)](#), we anticipate that these proposals will eventually be a most valuable tool to obtain a deeper insight in the basic physics of FQH fluids and synthetic topological matter, and to exploit the benefits of their atomic implementation in view of quantum information tasks ([Nayak et al., 2008](#)).

Dynamical synthetic gauge fields

In all of the above discussions, the vector potential appearing in Eqs. (1) and (2) was assumed to have a constant value, corresponding to a classical, externally imposed background field. Entirely new effects can appear once the vector potential is imbued with its own dynamics.

Dynamical vector potentials and Peierls phases

In the first proposal for continuum systems ([Edmonds et al., 2013](#)), a density-dependent vector potential was anticipated to arise from interaction-induced energy shifts of the internal atomic states involved in the optical transitions generating the Berry phase. Among the observable consequences, density-dependent persistent currents in ring geometries and chiral solitons were pointed out. Along similar lines, [Ballantine et al. \(2017\)](#) proposed to replace one of the optical fields generating the Berry phase by a multimode cavity field. The density of the atoms can then act back on the cavity field, which—due to its multimode character—can acquire a spatial dependence. In this way, the equivalent of the celebrated Meissner effect can be generated, whereby a magnetic field is expelled from the atom-cloud sample, see [Fig. 5](#).

Fig. 4 Chiral motion of two interacting atoms in a Harper–Hofstadter ladder, where each plaquette is pierced by a synthetic magnetic flux Φ . Upper panel: sketch of the trajectories for non-interacting ($U=0$) and interacting ($U \neq 0$) atoms. Lower panel: temporal dynamics along y displaying the chiral motion of the so-called skipping orbits. Copyright Springer Nature Ltd. 2017.

In lattice systems, a complementary direction is taken by turning the Peierls phase into a quantum-mechanical operator. This can happen, e.g., through density-dependent tunneling, where the complex hopping phase U_{ij} becomes a function $U_{ij}(\hat{n}_i, \hat{n}_j)$ of the atom number operators $\hat{n}_\ell = a_\ell^\dagger a_\ell$ at adjacent sites $\ell = i, j$. Such a situation can be generated by Floquet engineering (Meinert et al., 2016), as experimentally demonstrated in Görg et al. (2019), and it can naturally appear in regimes of very strong interactions or high occupation numbers (Dutta et al., 2011). Such a density-dependent tunneling has been proposed to lead to deformations of phase diagrams and the generation of novel phases such as pair superfluids (Dutta et al., 2011; Johnstone et al., 2019; Maik et al., 2013; Suthar et al., 2020) as well as to topological transitions in the ground state (Raventos et al., 2016).

In other schemes, the role of the Peierls phase can also be taken over by a second, independent atomic species. E.g., in an atomic mixture, an itinerant species can be coupled to the (pseudo-)spin degree of freedom of a second, kinetically frozen species (Kasper et al., 2021; Mil et al., 2020). By replacing the static hopping matrix by an additional quantum mechanical spin degree of freedom,

Fig. 5 Left: By suitably coupling the internal levels of ultracold atoms to a multi-mode cavity, a backaction from atoms onto the synthetic magnetic field can be engineered, where the spatial profile of the synthetic magnetic field varies depending on the atomic density. Right: Simulations of the atom-cavity system without (panels a,c,e) and with backaction (b,d,f). The backaction leads to an analog of the Meissner effect, where the magnetic field is expelled from the sample, leading to an extended region with $B = 0$. Reprinted figure with permission from Ballantine, KE, Lev, BL and Keeling, J (2017) Meissner-like effect for a synthetic gauge field in multimode cavity qed. *Physical Review Letters* 118: 045302. doi:10.1103/PhysRevLett.118.045302. Copyright 2017 by the American Physical Society.

$U_{i,j} \rightarrow S_{i,j}^\alpha$, $\alpha = x, y, z$, backaction phenomena between two different fields can lead, e.g., to topological and fractionalization effects such as a Peierls transition where an alternating pattern of strong and weak bonds dynamically emerges similar to polyacetylene (González-Cuadra et al., 2019, 2020). The additional possibilities offered by these experiments with atomic mixtures also enabled the observation of a Lamb shift effect in the atomic self energy. Similarly to the Lamb shift experienced by QED electrons due to their interaction with the quantum mechanical vector potential, an energy shift is induced here on one atomic species by their interactions with a second one (Rentrop et al., 2016).

Lattice gauge theories

In these approaches, the “vector potential” acquires its own dynamics, but the combined system of “particles” and “vector potential” does not necessarily respect the fundamental laws of QED, making it necessary to take similarities to magnetic fields with a grain of salt. To recover a full-fledged system of charged matter moving in a quantum mechanical electromagnetic field, additional care needs to be taken to enforce the $U(1)$ gauge symmetry that interlinks the two different types of dynamical degrees of freedom. In particular, the dynamics of the system needs to conserve the local symmetry that underpins QED, given by Gauss’ law, at all spatial coordinates and throughout the entire evolution time.

Although this task is highly challenging, groundbreaking experiments with local gauge symmetry have already been realized in Rydberg quantum simulators (Bernien et al., 2017; Surace et al., 2020), using Floquet techniques in optical lattices (Schweizer et al., 2019), exploiting angular momentum conservation in atomic mixtures (Mil et al., 2020) (proposed, e.g., in Stannigel et al., 2014; Zache et al., 2018; Zohar et al., 2013), as well as with energy penalties in optical superlattices (Halimeh et al., 2021; Yang et al., 2020; Zhou et al., 2021). Pioneering realizations have also been demonstrated in other platforms, in particular trapped ions (Kokail et al., 2019; Martinez et al., 2016; Nguyen et al., 2021), superconducting qubits (Klco et al., 2018, 2020; Mildenberger et al., 2022; Wang et al., 2022), and even classical electronic circuits (Riechert et al., 2021).

Most of these implementations focused on salient physical phenomena in one spatial dimension, and it is a current challenge to advance ultracold-atom lattice gauge theories into higher spatial dimensions (Zohar, 2022). In the future, these may enable, e.g., the investigation of strong-field effects on anomalous currents (Ott et al., 2020) as well as a range of new anomalous transport phenomena including the chiral magnetic effect (Fukushima et al., 2008; Kharzeev, 2014), the chiral vortical effect (Son and Zhitnitsky, 2004), or the conformal magnetic edge effect (Chernodub et al., 2019; Chu and Miao, 2018).

Conclusion

This review chapter summarized our point of view on the rich physics that can be obtained by synthetic static and dynamical gauge fields in cold-atom setups. We have reviewed the way synthetic magnetic fields can be engineered in such systems, discussed progress in controlled implementations of the integer, spin, and fractional quantum Hall effects, as well as some of the fascinating phenomena that appear when the atoms act back on the synthetic magnetic fields, without or with respecting gauge symmetry given by Gauss's law. These are, however, just some of the many facets of ongoing research in the broad context of synthetic gauge fields.

Promising implementations have been designed and realized in other synthetic quantum matter platforms. For example, topological photonic systems are presently one of the most active fields of research in optics, with potential technological applications such as efficient optical isolation and large-area, fabrication-disorder-robust topological lasers (Price et al., 2022). Synthetic magnetic field for photons are one of the key building blocks in this context and, analogously to the atomic case, can be realized in many different ways, from twisted optical cavities leading to an effective overall rotation (Schine et al., 2016), to static or time-dependent complex hopping phases (Hafezi et al., 2013; Roushan et al., 2017), to Floquet-like temporal modulations (Rechtsman et al., 2013). In combination with sizable photon-photon interactions arising from the optical nonlinearity of the underlying optical medium, a synthetic magnetic field for light may lead to the generation of novel states of photonic matter (Carusotto et al., 2020): baby versions of a quantum Hall fluid of light of a few photons have been recently realized (Clark et al., 2020). Other promising platforms are, e.g., analog implementations in trapped ions, where techniques similar to those for optical lattices have been developed to imprint Peierls phases (Bermudez et al., 2011; Manovitz et al., 2020), as well as universal quantum computers, where proposals for realizing fractional quantum Hall states (Rahmani et al., 2020) as well as experimental realizations of topological matter exist (Nigg et al., 2014; Satzinger et al., 2021; Semeghini et al., 2021).

All together, the examples discussed in this review illustrate the on-going exciting progress in the study of quantum Hall effects in cold atomic fluids as well as in related synthetic quantum matter platforms (Ozawa and Price, 2019). Beyond the remarkable achievements obtained so far, there are a lot of equally exciting open questions ahead of the community, as well as a number of potentially game-changing applications in quantum technologies (Nayak et al., 2008).

Abstract

Cold atomic gases of interacting bosons subject to rapid rotation and confined in anharmonic traps can theoretically exhibit analogues of the fractional quantum Hall effect for electrons in strong magnetic fields. In this setting the Coriolis force due to the rotation mimics the Lorentz force on charged particles but artificial gauge fields can also be obtained by coupling the internal structure of the atoms to light fields. The chapter discusses mathematical aspects of transitions to different strongly correlated phases that appear when the parameters of a model Hamiltonian are varied.

Key objectives

- Define a model Hamiltonian for trapped, interacting bosons in rapid rotation.
- Describe the confinement to the lowest Landau level for the kinetic part of the Hamiltonian.
- Discuss the yrast curve and the transition from an uncorrelated ground state in the lowest Landau level to fractional quantum Hall states.
- Discuss transitions from a Laughlin state to other strongly correlated states including giant vortex states in anharmonic traps.
- Derive density profiles of the strongly correlated states by means of Laughlin’s plasma analogy and rigorous mean field theory.

Notations and acronyms

Ω_{rot} :	rotational frequency
$\omega = \Omega_{\text{trap}} - \Omega_{\text{rot}}$:	frequency difference
Ω_{trap} :	frequency of a harmonic trap
$e^{\parallel}$:	spectral gap of the transverse confinement
$\mathcal{L} = \mathbf{e}_3 \cdot \mathbf{L}$:	transverse component of angular momentum
$V^{\parallel}$:	transverse confining potential
$\mathbf{L}$:	angular momentum
LLL	lowest Landau level

Introduction

Since the early 1990's it has been possible to isolate ultra-cold atomic gases of bosons in magneto-optical traps and maintain them in metastable states that can be modeled as ground states of many-body Hamiltonians with repulsive short range interactions. At sufficiently low temperatures the gas forms a Bose-Einstein condensate (BEC) (Ketterle and van Druten, 1996; Cornish et al., 2000) with all the atoms in the same state that can for dilute gases be described by an effective single particle equation of Gross-Pitaevskii type (Pethick and Smith, 2008; Pitaevskii and Stringari, 2016).

The atoms usually have no electric charge, but an artificial magnetic field can be imposed on them by a steady rotation of the trap. The analogy between the Lorentz and Coriolis forces implies that the Hamiltonian for neutral atoms in a rotating trap is formally identical to that of charged particles in a uniform magnetic field, apart from the centrifugal potential associated with the rotation. The analogy shows up, in particular, in the emergence of quantized vortices in cold rotating Bose gases (Bretin et al., 2004; Aftalion, 2006; Cooper, 2008; Fetter, 2009; Correggi et al., 2011), similar to those appearing in type II superconductors submitted to external magnetic fields.

An even more striking possibility is to employ rapid rotation to create phases with the characteristics of the fractional quantum Hall effect (FQHE) for electrons in very large magnetic fields (Prange and Girvin, 1987; Chakraborty and Pietiläinen, 1988, 1995; Störmer et al., 1999; Jain, 2007). In this regime, the Bose gas is no longer a condensate and mean-field theories fail to capture this phenomenon. A truly many-body description is required and strongly correlated states, such as the celebrated Laughlin state (Laughlin, 1983), may theoretically occur. This requires, however that the Coriolis force is very strong which inevitably means that the centrifugal force is also strong and may outweigh the trapping force. This can lead to an instability of the system unless special countermeasures are taken (Bretin et al., 2004; Schweikhard et al., 2004; Viefers, 2008; Fetter, 2009). In fact, the competing demands of a large rotation speed on the one hand, necessary for entering the FQHE regime, and of a sufficiently stable system on the other hand, have so far left the FQHE regime in rotating gases unattainable with current technology. Alternative methods to create artificial gauge fields have therefore been proposed and even partly realized in experiments (Dalibard et al., 2011; Roncaglia et al., 2011; Clark et al., 2020; Hauke and Carusotto, 2022).

From a theoretical point of view, however, the use of an anharmonic trapping potential to beat the destabilizing effect of the Coriolis force in a rotating trap remains a conceptually simple road to strongly correlated phases of Bosons with short range interactions. In this chapter, which is partly based on the lecture notes (Yngvason, 2014), we shall discuss how different phases may be produced by varying the parameters in this set-up. The same conclusions will apply to other experimental realizations of the Hamiltonian whenever they can be achieved.

The basic Hamiltonian

We consider first the following many-body Hamiltonian for N bosons of unit mass with position vectors $\mathbf{x}_{(1)}, \dots, \mathbf{x}_{(N)}$ in a rotating frame of reference:

$$H_N = \sum_{i=1}^N \left(-\frac{1}{2} \nabla_{(i)}^2 + V(\mathbf{x}_{(i)}) - \mathbf{L}_{(i)} \cdot \boldsymbol{\Omega} \right) + \sum_{1 \leq i < j \leq N} v(|\mathbf{x}_{(i)} - \mathbf{x}_{(j)}|). \quad (1)$$

Here $\boldsymbol{\Omega} = \Omega_{\text{rot}} \mathbf{e}_3$ is the angular velocity, with $\mathbf{e}_3$ the unit vector in the 3-direction and with $\Omega_{\text{rot}} \geq 0$, $\mathbf{L} = -i\mathbf{x} \times \nabla$ the angular momentum operator,

$$V(\mathbf{x}) = \frac{1}{2} \Omega_{\text{trap}}^2 r^2 + V^{\parallel}(x_3) \quad (2)$$

with $\mathbf{x} = (x_1, x_2, x_3)$, $r^2 = (x_1)^2 + (x_2)^2$, a quadratic trapping potential in the 12-plane, $V^{\parallel}$ a confining positive potential in the 3-direction, and v the pair interaction potential, assumed to be ≥ 0 . Units have been chosen so that Planck constant $\hbar$ as well as the particle mass is 1.

It is convenient to define the gauge field as

$$\mathbf{A}(\mathbf{x}) = \Omega_{\text{trap}}(x_2, -x_1, 0) \quad (3)$$

and write the Hamiltonian (1) as

$$H_N = \sum_{j=1}^N \left\{ \frac{1}{2} (i\nabla_{(j)} + \mathbf{A}(\mathbf{x}_{(j)}))^2 + \omega \mathbf{e}_3 \cdot \mathbf{L}_{(j)} + V^{\parallel}(x_3) \right\} + \sum_{i < j} v(|\mathbf{x}_{(i)} - \mathbf{x}_{(j)}|) \quad (4)$$

with¹

$$\omega = \Omega_{\text{trap}} - \Omega_{\text{rot}}. \quad (5)$$

We are interested in the case that $\omega > 0$ is small and Ω_{rot} (hence also Ω_{trap}) is large.

¹Alternatively, one can define $\mathbf{A}(\mathbf{x}) = \Omega_{\text{rot}}(-x_2, x_1, 0)$ in which case $\omega \mathbf{e}_3 \cdot \mathbf{L}$ is replaced by $\frac{1}{2} (\Omega_{\text{trap}}^2 - \Omega_{\text{rot}}^2) r^2$.

Confinement to the lowest Landau level

The 1-particle case

The single-particle Hamiltonian

$$H_1 = \frac{1}{2}(\mathbf{i}\nabla_{\perp} + \mathbf{A}(\mathbf{x}))^2 + \omega\mathcal{L} - \frac{1}{2}\partial_3^2 + V^{\parallel}(x_3) \quad (6)$$

with the notation $\mathcal{L} = \mathbf{e}_3 \cdot \mathbf{L}$ and $\nabla_{\perp} = (\partial_1, \partial_2)$, is a sum of three commuting operators,

$$\frac{1}{2}(\mathbf{i}\nabla_{\perp} + \mathbf{A}(\mathbf{x}))^2 \quad (7)$$

$$\omega\mathcal{L} \quad (8)$$

$$-\frac{1}{2}\partial_3^2 + V^{\parallel}(x_3). \quad (9)$$

The first operator, $\frac{1}{2}(\mathbf{i}\nabla_{\perp} + \mathbf{A}(\mathbf{x}))^2$, has the form of a magnetic Hamiltonian with the *Landau spectrum*

$$\left(n + \frac{1}{2}\right)2\Omega_{\text{trap}}, \quad n = 0, 1, 2, \dots \quad (10)$$

The spectrum of $\omega\mathcal{L}$ is

$$\ell\omega, \quad \ell = 0, \pm 1, \pm 2 \dots \quad (11)$$

and $-\frac{1}{2}\partial_3^2 + V^{\parallel}(x_3)$ has a spectral gap, $e^{\parallel} > 0$, above its ground state.

The energy of (6) is minimized in states with $n = 0$, i.e., in the lowest Landau level (LLL) of the magnetic Hamiltonian. Moreover, in the lowest energy state the motion in the x_3 -direction is ‘frozen’ in the ground state of $h^{\parallel}$. Confinement to the LLL in the N -particle context, taking the repulsive interaction into account, is discussed in Subsection ‘The N -particle case, contact interaction’ below.

From now on we focus on the 2-dimensional motion in the 12-plane and choose units so that $\Omega_{\text{trap}} = 1$.

Complex notation and Bargmann space

It is convenient to adopt complex notation for the position variables. Replacing (x_1, x_2) by the complex coordinate $z = x_1 + ix_2$ and denoting $\partial = \frac{1}{2}(\partial_1 - i\partial_2)$, $\bar{\partial} = \frac{1}{2}(\partial_1 + i\partial_2)$ we can write

$$\frac{1}{2}(\mathbf{i}\nabla_{\perp} + \mathbf{A}(\mathbf{x}))^2 = 2\left(\hat{a}^{\dagger}\hat{a} + \frac{1}{2}\right) \quad (12)$$

with

$$\hat{a}^{\dagger} := \frac{1}{2}(-2\partial + \bar{z}), \quad \hat{a} := \frac{1}{2}(2\bar{\partial} + z). \quad (13)$$

These operators satisfy the canonical commutation relations

$$[\hat{a}, \hat{a}^{\dagger}] = 1. \quad (14)$$

The operators

$$\hat{b}^{\dagger} := \frac{1}{2}(-2\bar{\partial} + z), \quad \hat{b} := \frac{1}{2}(2\partial + \bar{z}) \quad (15)$$

also satisfy the canonical commutation relations and commute with $\hat{a}$ and $\hat{a}^{\dagger}$. They correspond to a replacement $\mathbf{A} \rightarrow -\mathbf{A}$:

$$\frac{1}{2}(\mathbf{i}\nabla_{\perp} - \mathbf{A}(\mathbf{x}))^2 = 2\left(\hat{b}^{\dagger}\hat{b} + \frac{1}{2}\right). \quad (16)$$

Moreover,

$$\hat{b}^{\dagger}\hat{b} - \hat{a}^{\dagger}\hat{a} = z\partial - \bar{z}\bar{\partial} = \mathcal{L}. \quad (17)$$

Hence the eigenvalues of $\hat{a}^{\dagger}\hat{a}$ are infinitely degenerate and the degenerate eigenstates can be labeled by eigenvalues of either $\hat{b}^{\dagger}\hat{b}$ or $\mathcal{L}$.

The lowest eigenvalue of $\hat{a}^{\dagger}\hat{a}$ is zero so the eigenfunctions $\psi(z, \bar{z})$ in the LLL are solutions of the equation $\hat{a}\psi = 0$, i.e.,

$$\bar{\partial}\psi(z, \bar{z}) = -\frac{1}{2}z\psi(z, \bar{z}). \quad (18)$$

This means that

$$\psi(z, \bar{z}) = \varphi(z) \exp(-|z|^2/2) \quad (19)$$

with $\bar{\partial}\varphi(z) = 0$, i.e., φ is an analytic (holomorphic) function of z .

The LLL can thus be regarded as the Bargmann space $\mathcal{B}$ (Bargmann, 1961; Girvin and Jach, 1984) of analytic functions φ such that

$$\langle \varphi, \varphi \rangle := \int |\varphi(z)|^2 \exp(-|z|^2) d^2z < \infty \quad (20)$$

where d^2z denotes the Lebesgue measure on $\mathbb{C}$ (regarded as $\mathbb{R}^2$).

The Bargmann space is a Hilbert space with scalar product

$$\langle \varphi \psi \rangle := \int \bar{\varphi}(z) \psi(z) \exp(-|z|^2) d^2z. \quad (21)$$

On $\mathcal{B}$ the angular momentum operator is $\mathcal{L} = z\partial$. Moreover, for $\varphi \in \mathcal{B}$,

$$\langle \varphi, \mathcal{L}\varphi \rangle = \int (|z|^2 - 1) |\varphi(z)|^2 \exp(-|z|^2) d^2z. \quad (22)$$

The eigenvalues of $\mathcal{L}$ restricted to $\mathcal{B}$ are $\ell = 0, 1, 2, \dots$ with corresponding normalized eigenfunctions

$$\varphi_\ell(z) = (\pi \ell!)^{-1/2} z^\ell. \quad (23)$$

By (22) the probability density $|\varphi_\ell(z)|^2 e^{-|z|^2}$ is localized around $|z| = \sqrt{\ell + 1}$.

The N-particle case, contact interaction

For N bosons in the LLL the relevant Hilbert space is

$$\mathcal{B}_N = \mathcal{B}^{\otimes_{\text{sym}} N}, \quad (24)$$

i.e., it consists of symmetric, analytic functions ψ of $z_1, \dots, z_N$ such that

$$\int_{\mathbb{C}^N} |\psi(z_1, \dots, z_N)|^2 \exp\left(-\sum_{j=1}^N |z_j|^2\right) d^2z_1 \dots d^2z_N < \infty. \quad (25)$$

As next we take the interaction $\sum_{1 \leq i < j \leq N} v(|\mathbf{x}_i - \mathbf{x}_j|)$ into account.

For short range, nonnegative interaction potentials v it was proved in (Lewin and Seiringer, 2009) that under suitable conditions on N , v and ω :

- The ground state of (6) is effectively confined to the LLL in the 12-variables and in the 3-direction to the ground state of (9).
- The interaction potential v can be replaced by a contact interaction (pseudopotential) in the 12-variables of the form $g\delta(z_i - z_j)$ with a coupling constant

$$g = a \cdot \sqrt{e^\parallel} \int |\chi|^4 \quad (26)$$

where a is the s -wave scattering length of the potential v and χ the ground state wave function of (9).

Precise statements are contained in Theorems 1 and 2 in Lewin and Seiringer (2009). For the emergence of the pseudopotential see also (Seiringer and Yngvason, 2020), Theorem 2. Since wave functions in the Bargmann space $\mathcal{B}_N$ are analytic, the 2-body contact potential $\delta(z_i - z_j)$ is well defined and, in fact, given by a bounded operator: Defining δ_{12} on $\mathcal{B}_2$ by

$$\delta_{12}\varphi(z_1, z_2) = \frac{1}{2\pi} \varphi\left(\frac{1}{2}(z_1 + z_2), \frac{1}{2}(z_1 + z_2)\right), \quad (27)$$

a simple computation, using the analyticity of φ , shows that

$$\langle \varphi, \delta_{12}\varphi \rangle = \int_{\mathbb{C}} |\varphi(z, z)|^2 \exp(-2|z|^2) d^2z. \quad (28)$$

Thus the formal $\delta(z_i - z_j)$ can be replaced by the projection operator δ_{ij} . The effective Hamiltonian on the LLL can be written as.

$$H_N^{\text{LLL}} = \omega \mathcal{L}_N + g \mathcal{I}_N \quad (29)$$

with

$$\mathcal{L}_N = \sum_{i=1}^N z_i \partial_i \quad \mathcal{I}_N = \sum_{i < j} \delta_{ij}. \quad (30)$$

We denote its ground state energy by $E_N^{\text{LLL}}(\omega, g)$.

Writing $v(\mathbf{x}) = v_a(\mathbf{x}) = a^{-2} v_1(\mathbf{x}/a)$ and keeping v_1 fixed while varying a , we denote by $E_N(\omega, a)$ the ground state energy of (1) with $N \times$ the lowest energy of (7) and (9) subtracted. Then Theorem 1 in Lewin and Seiringer (2009) states that

$$\lim \frac{E_N(\omega, a)}{E_N^{\text{LLL}}(\omega, g)} = 1 \quad (31)$$

in a limit where

$$(Ng\omega)^{1/2} \ll \min\{\Omega_{\text{trap}}, e^\parallel\}. \quad (32)$$

Fig. 1 The joint spectrum of $\mathcal{L}_N$ and $\mathcal{I}_N$. Adapted from Lewin M, Seiringer R (2009) Strongly correlated phases in rapidly rotating Bose gases. *Journal of Statistical Physics* 137: 1040–1062.

Moreover, in the same limit also the ground state converges to its projection onto the LLL (Theorem 2 in Lewin and Seiringer (2009)).

The yrast curve

An important property of the Hamiltonian (29) is that the operators $\mathcal{L}_N$ and $\mathcal{I}_N$ commute. The lower boundary of (the convex hull of) their joint spectrum in a plot with angular momentum as the horizontal axis is called the yrast curve. See Fig. 1 and Viefers (2008) for its qualitative features.

As a function of the eigenvalues L of $\mathcal{L}_N$ the yrast curve $I(L)$ is decreasing from $I(0) = (4\pi)^{-1}N(N-1)$ to $I(N(N-1)) = 0$. The monotonicity follows from the observation that if a simultaneous eigenfunction of $\mathcal{L}_N$ and $\mathcal{I}_N$ is multiplied by the center of mass, $(z_1 + \dots + z_N)/N$, the interaction is unchanged while the angular momentum increases by one unit.

For a given ratio ω/g the ground state of (29) (in general not unique) is determined by the point(s) on the yrast curve where a supporting line of the curve has slope $-\omega/g$. The ground state energy is

$$E(N, \omega, g) = \min_L (\omega L + gI(L)). \quad (33)$$

The filling factor of a state with angular momentum L is defined as

$$\nu = \frac{N(N-1)}{2L} = \frac{N}{N_v} \quad (34)$$

where $N_v = 2L/(N-1)$ is called the number of vortices see Cooper (2008), Sec. 2.4. The filling factor of the ground state depends on the ratio ω/g and varies from ∞ to 0 as the ratio decreases and the angular momentum increases. Note the difference to the fermionic case, where the maximal filling factor in a fixed Landau level is 1.

Spectral gaps

For every value of the angular momentum L the interaction operator $\mathcal{I}_N$ has a nonzero spectral gap above 0

$$\Delta_N(L) = \inf\{\text{spec } \mathcal{I}_N|_{\mathcal{L}_N=L} \setminus \{0\}\} > 0. \quad (35)$$

This follows simply from the fact that states with a given eigenvalue L correspond to the finite dimensional space of symmetric homogeneous polynomials of degree L and contains states with strictly positive interaction energy. (Take for example, $(\text{const.}) \sum_j z_j^L$.) The gap, and hence the Yrast curve $I(L)$, are monotonously decreasing with L for the reason already mentioned: The angular momentum of an eigenstate of $\mathcal{I}_N$ can be increased by one unit by multiplying the wave function with the center of mass coordinate

$(z_1 + \dots + z_N)/N$. This does not change the interaction energy and leads to a family of ‘daughter states’ for each state on the yrast curve. There is numerical (see e.g., Viefers et al., 2000; Regnault et al., 2006) and some theoretical evidence that

$$\Delta_N(L) \geq \Delta_N(N(N-1)-N) = \min_{L' \leq N(N-1)} \Delta_N(L') =: \Delta > 0 \quad (36)$$

for all L with Δ independent of N but this is still not proved. (Proofs in a simplified setting can be found in Nachtergaele et al. (2020); Warzel and Young (2021a,b)) We shall call the validity of (36) the *spectral gap conjecture*.

The uncorrelated (Gross-Pitaevskii) regime

A rough estimate for the radius R of the system, assuming that the kinetic and interaction energy of (29) are of the same order of magnitude, gives

$$R \sim (Ng/\omega)^{1/4} \quad \text{and} \quad L \sim N\Omega R^2 \sim N(Ng/\omega)^{1/2}. \quad (37)$$

Thus, if $\omega/g \gg N^{-1}$ then $L \ll N^2$ and $\nu \gg 1$. In this case the ground state can be shown to be well described by an uncorrelated product state $(\varphi^{\text{GP}})^{\otimes N}$ where $N^{1/2}\varphi^{\text{GP}}$ minimizes the Gross-Pitaevskii energy functional on Bargmann space (Aftalion et al., 2006; Aftalion and Blanc, 2008)

$$\mathcal{E}^{\text{GP}}[\varphi] = \omega \langle \varphi, \mathcal{L}\varphi \rangle + \frac{g}{2} \int_{\mathbb{C}} |\varphi(z)|^4 \exp(-2|z|^2) d^2z \quad (38)$$

under the condition $\int |\varphi|^2 \exp(-|z|^2) d^2z = N$ with energy

$$E_N^{\text{GP}}(\omega, g) = NE_1^{\text{GP}}(\omega, Ng). \quad (39)$$

More precisely, the following holds (Lieb et al., 2009):

Theorem 1 (GP limit theorem in LLL). *For every $c > 0$ there is a $C < \infty$ such that*

$$E_N^{\text{GP}}(\omega, g) \geq E_N(\omega, g) \geq E_N^{\text{GP}}(\omega, g) \left(1 - C(g/N\omega)^{1/10}\right) \quad (40)$$

provided $gN/\omega > c$.

The lower bound covers the whole regime $L \ll N^2$, i.e., $\nu \gg 1$, but the GP description might have a wider range of applicability, see Fetter (2009) Section V C.

The proof of (1) uses similar techniques as in Lieb and Seiringer (2006) for the 3D GP limit theorem at fixed Ω and N a , in particular coherent states.

The analysis of the GP problem defined above is of interest in its own right (Aftalion and Blanc, 2008; Aftalion et al., 2006; Gérard et al., 2019). It is expected (see Aftalion, 2006; Viefers, 2008; Cooper, 2008; Fetter, 2009 and references therein) that for $\omega \rightarrow 0$ a vortex lattice is nucleated in the condensate. Namely, the zeroes of the analytic part of the GP minimizer in Bargmann space arrange on a triangular lattice in the bulk of the condensate, with a deformation at the edge (Aftalion et al., 2005; Ho, 2001; Aftalion and Blanc, 2008; Aftalion et al., 2006). Taking this fact into consideration in a local density approximation, one expects that

$$E_1^{\text{GP}}(\omega Ng) \sim E^{\text{TF}}(\omega Ng) \text{ in the limit } \omega \rightarrow 0 \text{ with } \omega \ll Ng \ll \omega^{-1} \quad (41)$$

where

$$E^{\text{TF}}(\omega, Ng) = \min \left\{ \int_{\mathbb{R}^2} \left((\omega|x|^2 - 1)\rho(x) + \frac{Ng}{2} e^{\text{Ab}} \rho(x)^2 \right) dx \mid \rho \geq 0, \int \rho = 1 \right\} \quad (42)$$

with

$$e^{\text{Ab}} \approx 1.16 \quad (43)$$

the Abrikosov constant (Abrikosov, 1957; Aftalion et al., 2006), i.e., the energy per area of a homogeneous vortex lattice. One also expects for the corresponding density of the GP minimizer

$$|u^{\text{GP}}|^2 \simeq \rho^{\text{TF}} = \frac{1}{Ng e^{\text{Ab}}} (\lambda - \omega|x|^2)_+ \quad (44)$$

in the same regime, where λ is a chemical potential ensuring normalization. The above expectations were rigorously proven in Nguyen and Rougerie (2022) (under the restricted assumption that $Ng \ll \omega^{-3/5}$).

These results suggest a formula distribution of quantized vortices in the condensate. Indeed,² writing the GP minimizer in the lowest Landau level in the manner

$$u^{\text{GP}}(z) = c \prod_{j=1}^m (z - a_j) e^{-\frac{|z|^2}{2}} \quad (45)$$

²Putting the following discussion on the same level of mathematical rigor as (44) remains a challenging open problem.

one finds (Aftalion et al., 2005; Ho, 2001)

$$\sum_{j=1}^m \delta_{a_j} = \frac{1}{4\pi} (4 + \Delta \log |u^{\text{GP}}|^2) \quad (46)$$

for the empirical distribution of the zeroes of u^{GP} , i.e., the locations of quantized vortices. Inserting the approximation (44) one finds

$$\sum_{j=1}^m \delta_{a_j} \simeq \frac{1}{\pi} + \frac{1}{4\pi} \Delta \log ((\lambda - \omega |x|^2)_+). \quad (47)$$

The first term, corresponding to a uniform density of vortices, dominates the asymptotics. The second one is an inhomogeneous correction, manifest mostly at the edge of the atomic cloud, see Aftalion et al. (2005), Aftalion and Blanc (2008), Aftalion et al. (2006) for more details.

The breakdown of the GP approximation is indicated by the number of vortices nucleated in the gas exceeding the total particle number. The above considerations indicate that this takes place when $g \gtrsim N\omega$, which marks the transition to a series of correlated many-body states, ending with a bosonic Laughlin function, as we discuss next.

Passage to the Laughlin state

As the filling factor decreases the ground state becomes increasingly correlated. The exact ground states are largely unknown (except for $L \leq N$ Papenbrock and Bertsch, 2001), but candidates of states with various rational filling factors (*composite fermion states*, *Moore-Read states*, *Read-Rezayi states*, ...) for energy upper bounds have been suggested and studied as discussed in the review article Cooper (2008).

If $\omega/g < \Delta/N^2$ one reaches the *Laughlin state* with filling factor $\frac{1}{2}$ whose wave function in Bargmann space is

$$\psi_{\text{Laughlin}}(z_1, \dots, z_N) = c \prod_{i < j} (z_i - z_j)^2. \quad (48)$$

It has interaction energy 0 and angular momentum $L = N(N-1)$. For an intuitive picture of the Laughlin state the following analogy may be helpful: The density $|\Psi_{\text{Laugh}}(z_1, \dots, z_N)|^2$ assigns probabilities to the possible configurations of N points moving in the plane. The points like to keep a distance at least of order 1 from each other because the factors $|z_i - z_j|^4$ strongly reduce the probability when the particles are close. On the other hand the damping due to the gaussian favors a tight packing of the ‘balls’ of size $O(1)$ around the individual particles. The motion is strongly correlated in the sense that if one ball moves, all the other have also to move in order to satisfy these constraints.

Adding an anharmonic potential

The limit $\omega \rightarrow 0$, keeping $\omega > 0$, is experimentally very delicate. For stability, but also to study new effects, we consider now a modification of the Hamiltonian (29) by adding a small anharmonic term:

$$H_N^{\text{LLL}} \rightarrow H_{k,N}^{\text{LLL}} := H_N^{\text{LLL}} + k \sum_{i=1}^N |z_i|^4 \quad (49)$$

with a new parameter $k > 0$. The potential $|z|^4$ can be expressed through $\mathcal{L}$ and $\mathcal{L}^2$ on Bargmann space, because with $\mathcal{L} = z\partial$ we have by partial integration, using the analyticity of φ :

$$\langle \varphi, \mathcal{L}\varphi \rangle = \int |\varphi(z)|^2 (|z|^2 - 1) \exp(-|z|^2) d^2z \quad (50)$$

and

$$\langle \varphi, \mathcal{L}^2\varphi \rangle = \int (|z|^4 - 3|z|^2 + 1) |\varphi(z)|^2 \exp(-|z|^2) d^2z. \quad (51)$$

Thus the modified Hamiltonian, denoted again by H_N^{2D} , can be written (up to an unimportant additive constant)

$$H_{k,N}^{\text{LLL}} = (\omega + 3k)\mathcal{L}_N + k \sum_{i=1}^N \mathcal{L}_{(i)}^2 + g\mathcal{I}_N \quad (52)$$

Fully correlated states

The Bargmann space $\mathcal{B}^N$ with the scalar product (25) is naturally isomorphic to the Hilbert space $\mathcal{H}_{\text{LLL}}^N \subset L^2(\mathbb{C}^{\otimes N}, d^{2N}z)$ consisting of wave functions of the form

$$\Psi(z_1, \dots, z_N) = \psi(z_1, \dots, z_N) \exp\left(-\sum_j |z_j|^2/2\right), \quad \psi \in \mathcal{B}_N \quad (53)$$

with the standard L^2 scalar product. The energy can accordingly be considered as a functional on this space,

$$\mathcal{E}[\Psi] = \int V_{\omega,k}(z) \rho_{\Psi}^{(1)}(z) + \langle \Psi, \mathcal{I}_N \Psi \rangle, \quad (54)$$

where $\rho_{\Psi}^{(1)}$ is the one-particle density of $\Psi \in \mathcal{H}_{\text{LLL}}^N$ with the normalization $\int \rho_{\Psi}^{(1)}(z) d^2z = N$ and the potential is

$$V_{\omega,k}(z) = \omega |z|^2 + k |z|^4. \quad (55)$$

Note that now $\omega < 0$ is allowed, provided $k > 0$.

We shall call states with vanishing interaction energy, i.e., $\Psi \in \ker \mathcal{I}_N$ fully correlated, because the particles stay away from each other in the sense that the wave function vanishes if $z_i = z_j$ for some pair $i \neq j$, in sharp contrast to a fully *uncorrelated* Hartree state. The fully correlated states in $\mathcal{H}_{\text{LLL}}^N$ are of the form

$$\Psi(z_1, \dots, z_N) = \phi(z_1, \dots, z_N) \Psi_{\text{Laugh}}(z_1, \dots, z_N) \quad (56)$$

with ϕ symmetric and analytic, and the Laughlin state

$$\Psi_{\text{Laugh}}(z_1, \dots, z_N) = c \prod_{i < j} (z_i - z_j)^2 e^{-\sum_{j=1}^N |z_j|^2/2}. \quad (57)$$

For the Hamiltonian *without* the anharmonic addition to the potential the Laughlin state is an *exact* fully correlated ground state with energy 0 and angular momentum $L_{\text{Laugh}} = N(N-1)$. This is not true for $k \neq 0$ because $\sum_{i=1}^N \mathcal{L}_{(i)}^2$ does not commute with $\mathcal{I}_N$. Note, however, that $\mathcal{L}_N$ still commutes with the Hamiltonian.

We now address the following question: Under what conditions is it possible to tune the parameters ω , g and k so that a ground state Ψ_0 of (52) becomes fully correlated for $N \rightarrow \infty$? The following theorem, proved in Rougerie et al. (2013) (see also Rougerie et al., 2014), gives sufficient conditions for this to happen. In order to state it as simply as possible we shall assume the ‘spectral gap conjecture’ of Subsection ‘Spectral gaps.’ This conjecture is not really needed, however, because it is possible to replace the assumed universal gap Δ by other gaps depending on N , ω and k , cf. Eq. (IV.5) in Rougerie et al. (2013).

Theorem 2 (Criteria for full correlation). With $P_{(\ker \mathcal{I}_N)^\perp}$ the projector onto the orthogonal complement of $\ker \mathcal{I}_N$ we have

$$\|P_{(\ker \mathcal{I}_N)^\perp} \Psi_0\| \rightarrow 0 \quad (58)$$

in the limit $N \rightarrow \infty$, $\omega, k \rightarrow 0$ if one of the following conditions holds:

- $\omega \geq 0$ and $\omega N^2 + k N^3 \ll g \Delta$.
- $0 \geq \omega \geq -2kN$ and $N(\omega^2/k) + \omega N^2 + k N^3 \ll g \Delta$.
- $\omega \leq -2kN$, $|\omega|/k \lesssim N^2$ and $k N^3 \ll g \Delta$
- $\omega \leq -2kN$, $|\omega|/k \gg N^2$ and $|\omega|/N \ll g \Delta$

Note: For $k = 0$ the first item is just the sufficient condition for the passage to the Laughlin state, $\omega/g < \Delta/N^2$, while the other conditions are void because $\omega < 0$ is only allowed if $k > 0$.

A proof of the Theorem is given in Section V of Rougerie et al. (2013). It is based on two estimates:

- A lower bound for the ground state energy at fixed angular momentum L :

$$E_0(L) \geq (\omega + 3k)L + k \frac{L^2}{N}. \quad (59)$$

- An upper bound for the energy of suitable trial functions.

The first bound (59) is quite simple; it follows essentially from the inequality

$$\sum_i \mathcal{L}_{(i)}^2 \geq \frac{1}{N} \left(\sum_i \mathcal{L}_{(i)} \right)^2 \quad (60)$$

that holds because $\mathcal{L}_{(i)}$ and $\mathcal{L}_{(j)}$ commute for any i, j .

The upper bound is achieved by means of trial states of the form ‘giant vortex times Laughlin,’ namely, with $m \geq 0$ and $c_{m,N}$ a normalization constant,

$$\Psi_{\text{gv}}^{(m)}(z_1, \dots, z_N) = c_{m,N} \prod_{j=1}^N z_j^m \prod_{i < j} (z_i - z_j)^2 e^{-\sum_{j=1}^N |z_j|^2 / 2} \quad (61)$$

These are special ‘quasi hole’ states (Laughlin, 1983) but for $m \gtrsim N$, i.e., $mN \gtrsim N^2$, the label ‘giant vortex’ appears more appropriate.³

The energy of a trial state of the form (61) can be estimated using properties of the angular momentum operators and the radial symmetry in each variable of the gaussian measure with the pre-factor $\prod_{j=1}^N |z_j|^{2m}$. The computation is presented in Eqs. (V3)–(V7) in Rougerie et al. (2013). Optimizing the estimate over m leads to

$$m_{\text{opt}} = \begin{cases} 0 & \text{if } \omega \geq -2kN \\ \frac{|\omega|}{2k} - N & \text{if } \omega < -2kN. \end{cases} \quad (62)$$

This is consistent with the picture that the Laughlin state is an approximate ground state in the first two cases of Theorem 1, in particular for negative ω as long as $|\omega|/k \lesssim N$. The angular momentum remains $O(N^2)$ in these cases.

When $\omega < 0$ and $|\omega|/(kN)$ becomes large the angular momentum is approximately

$$L_{\text{qh}} := N|\omega|/k \gg N^2, \quad (63)$$

much larger than for the Laughlin state. A further transition at $|\omega|/k \sim N^2$ is manifest through the change of the subleading contribution to the energy of the trial functions. Its order of magnitude changes from $O(kN^3)$ to $O(|\omega|N)$ at the transition.

To gain further insights into the physics of the transition we consider the particle density of the trial wave functions. This analysis (Rougerie et al., 2014) is based on Laughlin’s ‘plasma analogy’ where the N -particle density is written as a Gibbs distribution of a 2D Coulomb gas Laughlin (1983). This distribution can be studied in a rigorous mean field limit which brings out the essential features of the single particle density for large N .

The N -particle density as a Gibbs measure

We denote $(z_1, \dots, z_N)$ by Z for short and consider the scaled N particle density (normalized to 1)

$$\rho_{N,m}(Z) := N^N |\Psi_{\text{gv}}^{(m)}(\sqrt{N}Z)|^2. \quad (64)$$

We can write

$$\begin{aligned} \rho_{N,m}(Z) &= Z_{N,m}^{-1} \exp \left(\sum_{j=1}^N (-N|z_j|^2 + 2m \log |z_j|) + 4 \sum_{i < j} \log |z_i - z_j| \right) \\ &= Z_{N,m}^{-1} \exp \left(-\frac{1}{T} \mathcal{H}_{N,m}(Z) \right), \end{aligned}$$

with $T = N^{-1}$ and

$$\mathcal{H}_{N,m}(Z) = \sum_{j=1}^N \left(|z_j|^2 - \frac{2m}{N} \log |z_j| \right) - \frac{4}{N} \sum_{i < j} \log |z_i - z_j| \quad (65)$$

Plasma analogy and mean field limit

The Hamilton function $\mathcal{H}_{N,m}(Z)$ is that of a classical 2D Coulomb gas (‘plasma,’ one-component ‘jellium’) in a uniform background of opposite charge and with a point charge $(2m/N)$ at the origin, corresponding respectively to the $|z_i|^2$ and the $-\frac{2m}{N} \log |z_j|$ terms.

The probability measure $\rho_{N,m}(Z)$ minimizes the free energy functional

³Note that mathematically and physically these states are quite different from the *uncorrelated* giant vortex states in the GP theory of rotating Bose gases discussed in Correggi et al. (2011).

$$\mathcal{F}(\rho) = \int_{\mathbb{R}^{2N}} \mathcal{H}_{N,m}(Z) \rho(Z) + T \int_{\mathbb{R}^{2N}} \rho(Z) \log \rho(Z) \quad (66)$$

for this Hamiltonian at $T = N^{-1}$.

The $N \rightarrow \infty$ limit is in this interpretation a mean field limit where at the same time $T \rightarrow 0$. It is thus not unreasonable to expect that for large N , and in an appropriate sense,

$$\rho_{N,m} \approx \rho^{\otimes N} \quad (67)$$

with a one-particle density ρ minimizing a mean field free energy functional.

The mean field free energy functional is defined as

$$\mathcal{E}_{N,m}^{\text{MF}}[\rho] := \int_{\mathbb{R}^2} W_m \rho - 2 \int_{\mathbb{R}^2} \int_{\mathbb{R}^2} \rho(z) \log |z - z'| \rho(z') + N^{-1} \int_{\mathbb{R}^2} \rho \log \rho \quad (68)$$

with

$$W_m(z) = |z|^2 - 2 \frac{m}{N} \log |z|. \quad (69)$$

It has a minimizer $\rho_{N,m}^{\text{MF}}$ among probability measures on $\mathbb{R}^2$ and this minimizer is in Rougerie et al. (2014) proved to be a good approximation for the scaled 1-particle density of the trial wave function, i.e., for

$$\rho_{N,m}^{(1)}(z) := \int_{\mathbb{R}^{2(N-1)}} \rho_{N,m}(z, z_2, \dots, z_N) d^2 z_2 \dots d^2 z_N.$$

(Recall the scaling: This density in the scaled variables z is normalized so that its integral is 1. The corresponding density in the physical, unscaled variables $\zeta = \sqrt{N}z$ has total mass N .)

Formulas for the mean field density

The picture of the 1-particle density that arises from asymptotic formulas for the mean-field density, valid for large N , is as follows:

If $m \leq N^2$, then ρ_m^{MF} is well approximated by a density $\hat{\rho}_m^{\text{MF}}$ that minimizes the mean field functional without the entropy term $N^{-1} \int_{\mathbb{R}^2} \rho \log \rho$. This density takes a constant value $(2\pi)^{-1}$ on an annulus with inner and outer radii (in the scaled variables!)

$$R_- = (m/N)^{1/2}, \quad R_+ = (2 + m/N)^{1/2}$$

and is zero otherwise. The constant value is a manifestation of the incompressibility of the density of the trial state.⁴

For $m \gtrsim N^2$ the entropy term becomes important and may dominate the electrostatic interaction term $\iint \rho(z) \log |z - z'| \rho(z')$. The density is well approximated by a gaussian profile $\rho^{\text{th}}(z) \sim |z|^{2m} \exp(-N|z|^2)$ that is centered around $(m/N)^{-1/2}$ but has maximal value $\sim N/m^{1/2} \ll 1$ for $m \gg N^2$.

Thus, as the parameters ω and k tend to zero and N is large, the qualitative properties of the optimal trial wave functions exhibit different phases:

- For positive ω , more generally for $\omega/k > -2N$, the Laughlin state is the ground state.
- When ω is negative and $|\omega|$ exceeds $2kN$ the state changes from a pure Laughlin state to a modified Laughlin state with a ‘hole’ in the density around the center.
- A further transition occurs at $|\omega| \sim kN^2$. The density profile changes from being ‘flat’ to an annulus with a Gaussian shape in the radial variable.

The qualitative features of these three phases are indicated in Fig. 2. An intuitive understanding of the transitions may be obtained by employing the previous picture of the points z_i as being the centers of essentially non overlapping balls of size $O(1)$. From the point of view of the plasma analogy the particles stay away from each other because of the repulsive Coulomb potential between them, while the attractive external potential due to the uniformly charged background keeps them as close together as possible. Modifying the wave function by a factor $\prod_j z_j^m$ has the effect of a repulsive charge of magnitude m at the origin that pushes the particles (collectively!) away from the origin, creating a ‘hole.’ The effect of such a hole on the energy of the wave function in the trap potential is to increase the energy if ω is positive. Hence the ground state will not have a hole. If $\omega < 0$ the effective trapping potential has a Mexican hat shape with a minimum away from the origin, but since no ball can move without ‘pushing’ all the other balls, it is too costly for the system to take advantage of this as long as k stays above the critical value $|\omega|/2N$. For smaller k a hole is formed. The balls remain densely packed until the minimum of the Mexican hat potential moves so far from the origin that an annulus of width $O(1)$ at the radius of the minimum can accommodate all N balls. This happens for $k \lesssim |\omega|/N^2$. For smaller k (larger radius) the balls need not be tightly packed in the annulus and the average local density decreases accordingly.

⁴Note that these is a statement about the mean field density that is a good approximation, suitably averaged, to the true 1-particle density for large N . See Ciftja (2006) for numerical calculations of the true density of the Laughlin state for $N = 400$.

Fig. 2 The three phases of the density $\rho_{N,m}^{(1)}$ (not to scale).

Conclusion

The main conclusion from the analysis presented above of the ground states in the lowest Landau level generated by rapid rotation can be summarized as follows:

- For the Hamiltonian (29) the parameter regime $g \ll N\omega$, i.e., $L \ll N^2$, can be described by Gross-Pitaevskii theory in the LLL.
- To enter the ‘fully correlated’ regime with $L \geq N(N-1)$ we have studied the Hamiltonian (52) with a quadratic plus quartic trap where the rotational frequency can exceed the frequency of the quadratic part of the trap, i.e., the frequency difference ω can be negative.
- Through the analysis of trial states for energy upper bounds, and simple lower bounds, we have obtained criteria for the ground state to be fully correlated in an asymptotic limit. The lower bounds, although not sharp, are of the same order of magnitude as the upper bounds.
- The particle density of the trial wave functions can be analyzed using Laughlin’s plasma analogy combined with rigorous mean field limits. The character of the ground state density changes at $|\omega|/k = O(N)$ and again at $|\omega|/k = O(N^2)$.

Abstract

In several solid-state systems, (charge) neutral currents originating from different “valleys” of an energy band can flow in different spatial directions and lead to long-ranged “valley currents.” Graphene (Gr), a monolayer of carbon atoms with broken time-reversal symmetry (T) and/or inversion symmetry (P), is a promising stage for this phenomenon, where (2 + 1)-dimensional Dirac fermion with an internal degree of freedom (“flavor”) plays a crucial role in the low-energy limit. Based on experiments, such a neutral current can be realized and detected by all-electrical nonlocal measurements in hexagonal-boron-nitride (hBN)/Gr superlattices, which are investigated herein.

Key points

- Valley currents are novel charge-neutral currents in solid states.
- Graphene superlattice is an ideal stage for manipulating and detecting valley currents.
- Dirac fermions emerge in graphene in the low-energy limit as quasiparticles.
- The transport properties of graphene and its variants are described by Dirac fermion models.
- Nonlocal transport is an effective probe of charge-neutral currents.

Introduction

A valley is a quantum-mechanical degree of freedom built into electrons for several solid-state systems. A valley in an energy band is a degenerate local minimum (maximum) in the conduction (valence) band, referred to as K and K' in the case of graphene (Gr), corresponding to valley pseudospin states (Xiao et al., 2007).

Graphene, a monolayer of carbon atoms, is the “parent” of the novel promising class of quantum metamaterials, e.g., the emergence of “topological” current associated with a valley degree of freedom (Xiao et al., 2007; Xiao et al., 2010). Graphene is distinguished from its family members/two dimensional (2D) materials by its “relativistic” energy dispersion, rendering its quasiparticle identical to “(2 + 1)-dimensional Dirac fermion.” It has two valley pseudospin states (“flavors”), which transform into each other under spatial inversion. The broken inversion symmetry (P) induces valley-contrasted physics through the emergence of a “hot spot” for each valley where Berry curvatures accumulate (Xiao et al., 2007; Xiao et al., 2010). Nonlocal transport could be a Berry-phase-sensitive probe for detecting such a hot spot in hexagonal boron nitride (hBN)/Gr superlattices (Gorbachev et al., 2014; Komatsu et al., 2018; Lensky et al., 2015). Quantum valley current was also detected through nonlocal resistance in the quantum limit (Komatsu et al., 2018). This is based on the quantum Hall effect (QHE) but without magnetic-field/time-reversal symmetry (T) breaking (Haldane, 1988; Laughlin, 1981; Thouless et al., 1982).

The emergence of such “hot spot” and “valley current” in graphene needs a broken T and/or P. This can be achieved by applying a magnetic field and/or fabricating a heterostructure, such as hBN/Gr heterostructures, which are discussed below.

Overview

Graphene has attracted intense interest, especially in electronic systems, where charge carriers have a nodal/“Dirac-cone” shape with linear energy dispersion (Geim and Novoselov, 2007). Graphene exhibits novel charge carrier transport properties, including bipolar QHE, minimum metallic conductivity, and Klein tunneling. Typical data are shown in Fig. 1. Fig. 1A shows a sharp peak of the longitudinal resistance near zero gate bias, corresponding to the Dirac point (DP), which reflects the “Dirac-cone” of the energy dispersion. Bipolar QHE is also detected as magnetic field evolution of the resistance, as shown in Fig. 1B.

Graphene was discovered early in this century when it was exfoliated on SiO₂ (Geim and Novoselov, 2007). Graphene-based devices on SiO₂ are generally disordered, and their characteristics are inferior to those of the intrinsic ones. The quality of SiO₂-supported graphene has remained basically unchanged since its discovery. Although the exact nature of the scattering that

characterizes graphene devices remains unclear, an underlying substrate should play a crucial role. On SiO_2 , for example, the carrier mobility is limited by scattering from the charged surface state, impurities, substrate surface roughness, ripples, and SiO_2 surface optical phonons combined with fabrication residue on and/or under the graphene layer. Around the nodes of “Dirac cone”/DP, 2D electron gas (2DEG) has been broken up into the so-called “electron-hole” puddles due to substrate-induced disorder. Furthermore, charged impurities in the substrate or graphene–substrate interface can cause “self-doping” of 2DEG, resulting in a shift in the Dirac point. Therefore, there is a need for alternatives to SiO_2 .

Although suspension of graphene improves device quality (Bolotin et al., 2008), its geometry highly limits the architecture of the device, and this challenge needs to be overcome. Graphene superlattice structures, hBN/Gr(hBN), can overcome the above-mentioned challenge. Heterostructures based on hBN and graphene are a novel class of quantum metamaterials and devices.

hBN is a promising and ideal substrate dielectric (Watanabe et al., 2004). BN is an insulating analog of graphite, where boron (B) and nitrogen (N) atoms occupy the inequivalent sublattice sites in the Bernal structure. The difference in the onsite energies of the B and N atoms results in a large bandgap (~ 6 eV) and a small lattice mismatch (1.7%) with graphite. Due to the strong, in-plane, ionic bonding of the planar hBN structure, hBN is inert and expected to be free of dangling bonds or surface charge traps. Furthermore, the dielectric properties of hBN ($\epsilon \sim 3\text{--}4$ and $V_{\text{BreakDown}} \sim 1$ V/nm) and the surface optical phonon modes (twice larger in energy than the corresponding modes SiO_2) are also idealistic compared with those of SiO_2 .

hBN/Gr superlattices have the so-called “moiré superlattice” with a long-wavelength moiré pattern and inversion-symmetry (P) breaking, which is associated with the energy gap/hot spot at the charge-neutral point (CNP), and satellites of CNP emerge. This CNP corresponds to the DP introduced above, and the satellites to “higher-generation” DP. The moiré superlattice also induces an intriguing energy spectrum under a magnetic field, which is referred to as “Hofstadter’s butterfly.” When subject to a magnetic field, the resistance peaks result in first- and second-generation Landau fans, which are demonstrated below. The first generation corresponds to CNP, and the second generation is attributed to inversion-symmetry breaking and corresponds to the satellites of CNP.

Fig. 2 shows hBN/Gr(hBN) moiré superlattices, where single-layer graphene (SLG) and top/bottom hBN flakes are set by aligning the long edges of each flake.

In Fig. 3, the quantum Hall effect of the hBN/SLG superlattice is shown near DP (Fig. 3C), and the Landau-fan diagrams of Hofstadter's butterfly are observed (Figs. 3A and B). CNP is near $V_g = 0$, and the satellites are away from there. The satellite shows a clear (second-generation) Landau fan in the hole side (negative V_g) (Figs. 3A and B). The emergence of "massive" Dirac fermion is confirmed by the Arrhenius plots (Fig. 3D), which show the temperature dependence of the local resistance at DP and second Dirac points of CNP shown as a secondary Dirac point (SDP). In Fig. 3D, the gaps at DP and SDP were estimated as 32 meV and 14 meV, respectively, by linear fitting in the high-temperature region, which corresponds to the emergence of "massive" Dirac fermions with a "hot spot."

Generally, nonlocality in electronic devices refers to the emergence of a voltage across contacts "far away" from the path through which an excitation (charge) current is expected to flow. The first "giant" nonlocal resistance was detected in graphene under a magnetic field (Abanin et al., 2011), which faded out under zero magnetic fields. The origin of this phenomenon is still controversial. Herein, we focus on graphene device with a broken P (and unbroken T). This is realized in the graphene superlattice with hBN.

Inversion symmetry is broken by hBN, resulting in finite Berry curvature and bandgap in the momentum space (Xiao et al., 2007; Xiao et al., 2010). Analogous to a magnetic field controlling electron motion in real space, the Berry curvature can be interpreted as a finite magnetic field in momentum space, which also modifies the motion of electrons. The Berry curvature has opposite signs for the two valleys; thus, electrons belonging to different valleys flow in opposite directions under an electric field, even under a zero magnetic field. This is the origin of the bulk valley current.

In moiré superlattices, a long-wavelength moiré pattern develops, resulting in Hofstadter's butterfly under a magnetic field (Dean et al., 2013; Ponomarenko et al., 2013) (Fig. 3), where the hot spot emerges in the momentum space due to the broken inversion symmetry. The electrical current induced at one end of the H-bar induces a topological valley current in the transverse direction because of the hot spot, and this current is converted to a voltage drop at the other end of the H-bar through the inverse effect (Figs. 4–6). Recently, graphene superlattices due to the moiré structure have been intensively studied. Since the work of Bistritzer and MacDonald (2011a), Bistritzer and MacDonald (2011b) in particular, moiré bands/butterflies in bilayer graphene (BLG) have been extensively studied. They are analogous to those of SLG (Ponomarenko et al., 2013). BLG has a unique electronic structure quite different from that of SLG, and its bandgap can be tuned by applying an electric field perpendicular to the system. The two layers in BLG generally exhibit AB (Bernal) stacking. An example is shown in Fig. 6, where a long-wavelength moiré pattern stems from the small lattice mismatching as in the SLG case.

Herein, we analyze the experimental setting based on our device in Komatsu et al. (2018) (Fig. 4). Here, the Hall bar geometry and nonlocal resistance measurement setup were applied. Local and nonlocal resistances were measured using a low-frequency lock-in technique with minimized AC excitation. ρ_{xx} is the longitudinal resistivity for the current terminal (1, 4, shown as I14) and

the voltage terminal (6, 5, shown as V65), and R_{nl} is a nonlocal resistance for the current terminal (I62) and voltage terminal (V53) in Figs. 4A and B. In the nonlocal measurements, the charge current on the left (terminals 6 and 2) generates a valley current in its transverse direction, which is converted into a voltage on the right (terminals 5 and 3). The nonlocal resistance R_{nl} is defined as the voltage divided by the current. Fig. 4B shows ρ_{xx} (blue curve) and R_{nl} (red curve) as functions of V_g at 1.5 K and 0 T. Figs. 4C and D show the resistances with different terminal configurations of a six-terminal sample. The horizontal dotted lines show the theoretical values of the resistance based on the minimum edge-state model. As shown in Fig. 4E, the nonlocal resistance shows a thermally-activated behavior as in the conventional longitudinal resistance in Fig. 3D.

Li et al. (2020), reported R_{nl} of the order of the quantum resistance near DP. Fig. 5A shows an optical microscope image of hBN/SLG/hBN superlattice devices reported by Li et al. (2020), and Fig. 5B shows the local and nonlocal transport near DP. Graphene is aligned with both the top and bottom hBN layers in device I. In contrast, it is aligned with the top layer of hBN ($\theta \approx 0^\circ$) but misaligned ($\theta \approx 30^\circ$) with the bottom hBN in device II. R_{nl} approaches the quantum resistance in device I, but it is much smaller (60Ω) in device II. Therefore, device I should correspond to the experiment in Komatsu et al. (2018), which was reconfirmed here in Li et al. (2020). Fig. 5C shows the resistance with different terminal configurations.

Figs. 4 and 5 show nonlocal transport in hBN/SLG/hBN superlattices. To check the universality of this phenomenon, we studied hBN/BLG/hBN superlattices (Endo et al., 2019). Fig. 6 shows hBN/BLG/hBN superlattices. In both cases, R_{nl} of the order of kilo-Ohms (I14 V23) was observed. Fig. 6A shows an optical image of the hBN/BLG/hBN superlattice device, and the inset shows a schematic of the four-terminal device structure with the terminal numbers.

Key issues

In generic setting, nonlocality is conventionally attributed to the “Ohmic contribution” due to “stray charge currents,” which is expressed by the van der Pauw formula. In this study, the Ohmic contribution is much smaller than R_{nl} ; thus, is not the main factor influencing our observation. Furthermore, the scaling relation between ρ_{xx} and R_{nl} indicates the emergence of a bulk topological current (Abanin et al., 2009; Endo et al., 2019; Gorbachev et al., 2014; Komatsu et al., 2018). Such nonlocal resistance cannot be detected without a superlattice structure in the absence of a magnetic field.

A moiré superlattice with broken inversion symmetry causes the accumulation of hot spots with Berry curvature at CNP and harbors the satellites of CNP. We observed nonlocal resistance of the order of kilo-Ohms, which obeys a scaling relation (Abanin et al., 2009). This nonlocal resistance evolves from the quantum Hall effect but without magnetic field/time-reversal symmetry breaking, which is associated with the hot-spot-induced topological valley current. In other words, the nonlocal resistance is a Berry-phase-sensitive probe to detect hot spots in gapped Dirac materials with inversion-symmetry breaking.

At the low-temperature limit, on the other hand, a clear deviation from the scaling relationship was observed. Komatsu et al. (2018) attributed this to edge-mode conduction, which was also reconfirmed by Li et al. (2020). The detailed nature of this edge mode would be investigated in future studies.

Conclusion

Valley currents, particularly in graphene superlattices, are promising. There is a need for hybrid devices with quantum dots on such monolithic 2D materials as they have many application potentials. The profound nonlocality in hBN/Gr devices, which are sensitive probes for such a neutral degree of freedom as valleys, provides key information that cannot be obtained using conventional approaches.

Abstract

Topological phase is a new concept, that is independent of the standard phase classification by symmetry breaking, and is characterized by quantized quantities (topological numbers) of the gapped bulk which may not be always experimentally observable. Physical quantities to be measured are gapless excitations (edge states) near the boundaries of the systems. These low energy modes are stable against local perturbations protected by the bulk gap. This is the topological stability. The relation between the topological number of the bulk and the edge states is the bulk-edge correspondence. It has been first established for quantum Hall states. Today not only quantum but also many classical phenomena are recognized as under the control of the bulk-edge correspondence. Universality of the bulk-edge correspondence is extending rapidly over different areas. We also mentioned on the unique feature of the bulk-edge correspondence in topological pump and the extension for symmetry protected topological phases.

Key points

- Bulk-edge correspondence, that is a fundamental concept for topological phases, is explained.
- TKNN numbers, Chern numbers and a topological number of edge states are defined for integer quantum Hall effect and discussed.
- Topological pump and symmetry protected topological phases are mentioned from the bulk-edge correspondence.

Introduction

According to the standard characterization of physical phases, the order parameter, which is an experimental observable and reflecting specific symmetry breaking, is a key quantity. Finite magnetization due the rotational symmetry breaking in spin space is a typical example. The order parameter is extensive, that is, its value per volume (density) is finite when the system size is sufficiently large (in the thermodynamic limit). This naturally implies that its value as a density is independent of local perturbations such as effects of boundaries and finite number of local impurities.

On the other hand, as for the topological phase, which is a new way of description for material phases, there is no fundamental order parameter associated with the symmetry breaking that any experiments may access. Experimental observables for the topological phases are *localized states* (generic edge states) as we explain here. A surface sensitive experiment such as the angle resolved photoemission spectroscopy (ARPES) is a typical technique that has been effective for experimental characterization of topological phases (topological insulators). The edge states reflect topologically non-trivial bulk. Conversely bulk without any boundaries with non-trivial topological number implies edge states when one makes boundaries by dividing the system. This relation is the bulk-edge correspondence that has been realized as a key concept for the study of the topological phases for the decades.

Let us define the word “localized” for a open-particle state $\psi(x)$. It is localized if and only if it is normalizable as $\int d^d x |\psi_{\text{loc}}(x)|^2 < +\infty$ where x is a spatial coordinate in d -dimension. Otherwise it is extended (unnormalized) such as plane waves. If one considers a system with its spatial size L , total norm of the state $\int_{L^d} d^d x |\psi_{\text{ext}}(x)|^2$ diverges for the extended state $\psi_{\text{ext}}(x)$ in the limit $L \rightarrow \infty$. Or if one uses a system dependent normalization $\psi_L(x) = N^{-1/2} \psi_{\text{ext}}(x)$ ($N = \int_{L^d} d^d x |\psi_{\text{ext}}(x)|^2$), $\psi_L(x) \rightarrow 0$ everywhere ($L \rightarrow \infty$). Then $\psi_L(x)$ is useless, which is a physical meaning of *unnormalizability*. As is clear by this discussion, whether

Fig. 1 (a) Setup of Laughlin argument. (b), (c) Edge states on a cylinder. In this example, the unknown integer of the Laughlin argument is explicitly fixed as +2. Two states are passing through the system during the adiabatic process.

the state is extended or localized is well defined only in the infinite system. The bulk-edge correspondence is used for the infinite system with/without edges.¹

Although the bulk-edge correspondence is, in principle, independent of the translation symmetry, let us assume translation symmetry to make the discussion simple. By writing the translation by a as T_a , the translation invariance for the Hamiltonian implies $[T_a, H] = 0$ and all eigenstates of the Hamiltonian are also simultaneous eigenstate of T_a as $T_a \psi = \rho \psi$. Further the unitarity of the translation (conservation of the norm) implies $|\rho| = 1$. For an one-particle state ψ with energy ϵ , this is the Bloch theorem, that is, all states of the translation invariant system have to be extended since $|\psi(x)| = |\psi(y)|(x - y = na)$ for any integer n . Its energy ϵ belongs to energy bands. It is then also true, as a contrapositive, that localized states exist only for systems without translation invariance and its energy needs to be in the energy gaps (complement of the energy bands). Typical cases can be systems with boundaries or with impurities. Formally the bulk-edge correspondence is a relation between the states with different boundary conditions since the Bloch condition implies the periodic boundary condition and a system with boundary implies vanishing its value at the edges. It reminds us well-known Levinson's theorem in quantum mechanics and Friedel's sum rule where phase shifts of the scattering states (bulk) govern the number of bound states. This is one of the physical backgrounds of the bulk-edge correspondence.

Quantum Hall effects

Laughlin argument and edge states

Since the Laughlin argument (Laughlin, 1981) using a gauge invariance associated with a vector potential A (gauge field) to explain the integer quantum Hall effect (Klitzing et al., 1980) is fundamentally important for the bulk-edge correspondence, let us discuss it carefully. Conceptually the argument is also applied for various topological phases by introducing fictitious gauge field A_f and charge e_f associated with the minimum coupling for a spatial derivative $-i\hbar\nabla \rightarrow -i\hbar\nabla - e_f A_f$.

The setup of the Laughlin argument itself is topologically non trivial as putting two-dimensional electrons (charge $-e$) in a magnetic field on a cylinder (periodic boundary condition in y -direction) and open one in x -direction. Introducing the Aharonov-Bohm (AB) flux ϕ_y passing through the cylinder implies a shift of the vector potential $\bar{A} = A + \delta A$, $\delta A = (0, \frac{\phi_y}{L_y}, 0)$ as shown in Fig. 1. Note that $\int_D dS \cdot \text{rot} \delta A = \int_{\partial D} d\mathbf{r} \cdot \delta A = \phi_y$. Since the velocity of electrons in y -direction is written as $v_y = \partial_{\delta A_y} \hbar/e$ where the one-particle Hamiltonian $h = \frac{(p + eA)^2}{2m} = -\frac{\hbar^2}{2m} \left(\nabla + i \frac{2\pi}{\phi_0} A \right)^2$, $\text{rot} A = (0, 0, B)$ and $\phi_0 = \frac{h}{e}$ is a flux quantum, the current density j_y in x - y plane per unit width is written by the many particle Hamiltonian (without interaction) $H = \sum_j h(r_j)$ as $j_y = -\frac{1}{L_x L_y} \sum_j e v_y(r_j) = -\frac{1}{L_x} \partial_{\phi_y} H$ where r_j is a coordinate of the j -th electron. It implies the Hall current in $-y$ direction I_y (Fig. 1)

¹To distinguish the (localized) edge states from the extended states, one needs to take a limit $L \rightarrow \infty$ even with the open boundary condition. This is the infinite system with edges.

is written as $I_y \equiv -L_x \langle j_y \rangle_\Psi = \langle \partial_{\phi_y} H \rangle_\Psi$ where the expectation value is taken for a many particle state Ψ of the system (constructed from one-particle state ψ 's). Assuming the AB flux ϕ_y is adiabatically modified, it is given by the Feynman's theorem as

$$I_y = \frac{\partial E}{\partial \phi_y} \quad (1)$$

where $E = \langle H \rangle_\Psi$ is the energy of the snapshot many-particle ground state $\Psi(\phi_y)$, $H(\phi_y)\Psi(\phi_y) = \Psi(\phi_y)E(\phi_y)$.

The AB flux is locally gauged out by the (large) gauge transformation

$$U h(\bar{A}) U^\dagger = h(A), \quad U = e^{i2\pi \frac{\phi_y}{\phi_0} \frac{y}{L_y}}$$

$$\psi = U \bar{\psi} = e^{i2\pi \frac{\phi_y}{\phi_0} \frac{y}{L_y}} \bar{\psi}$$

where $h(\bar{A})\bar{\psi} = \bar{\psi}\epsilon$ and $h(A)\psi = \psi\epsilon$ with a one-particle energy ϵ . However, the periodic boundary condition for $\bar{\psi}$ implies a twisted boundary condition for ψ as $\psi(x, y) = e^{i\theta} \psi(x, y + L_y)$ with $\theta = 2\pi \frac{\phi_y}{\phi_0}$. It implies the wave function is generically discontinuous at $y = 0$ ($y = L_y$) where the system is glued to form a cylinder. It costs extra energy. Only when $\phi = \phi_0$, this mismatch vanishes and the effect of the Aharonov-Bohm ϕ_y is completely gauged out. It implies the system remains the same, or goes back to the initial state.

When the system size is sufficiently large ($L_y \rightarrow \infty$), one may replace the derivative in Eq. (1) as $\frac{\partial E}{\partial \phi} \rightarrow \frac{\Delta E}{\Delta \phi_0}$ noting that $\delta A_y \sim \frac{\phi_0}{L_y}$ is sufficiently small. According to Laughlin, the energy cost ΔE for this adiabatic process should be then followed by some number of states, say, (unknown) n states, are carried from the right to the left boundaries. Assuming the potential difference between the boundaries due to the external field as V_x , $\Delta E = -neV_x$. It simply results in

$$I_y = -\frac{neV_x}{\phi_0} = \sigma_{yx} V_x.$$

This implies the quantization of the Hall conductance as $\sigma_{xy} = -\sigma_{yx} = n \frac{e^2}{h}$ where the integer n is not fixed by the present gauge invariance argument.

Role of edge states

Although, the quantization of the Hall conductance is clear, its value n is not specified in the Laughlin argument. Actually it is given by the number of edge states passing through the Fermi energy, which was first pointed out by Halperin (Halperin, 1982). Let us repeat it in the cylindrical geometry. Taking a Landau gauge, $A = (0, Bx + \frac{\phi_y}{L_y}, 0)$, the one-particle wave function after the large gauge transformation is written as $\psi = U \bar{\psi} = e^{-ik_y y} \varphi(x - x_{k_y})$. It is a plane wave in y -direction and φ is a solution of the Schrödinger equation of the harmonic oscillator in x -direction localized near $x_{k_y} = \ell_B^2 k_y$ (if the system is infinite) where $\ell_B = \sqrt{\frac{h}{eB}}$ is a magnetic length. The periodic boundary condition of $\bar{\psi}$ implies the quantization of the shifted momentum as $k_y = \frac{2\pi}{L_y} \left(n - \frac{\phi_y}{\phi_0}\right)$, $n \in \mathbb{Z}$.

With boundaries in x -direction, let us consider soft boundaries to discuss the situation of the cylinder qualitatively. Then one needs to expand the wave function by those of the harmonic oscillator for each momentum k_y . Since the one-particle energies of the states centered far away outside from the position of the (soft boundaries) should be far above the Fermi energy, one may expect the one-particle energies of the states specified by the preserved momentum k_y are raised from the Landau levels as shown in Fig. 1 (b) and (c). Here we assume the continuity of the energy of the one-particle state as a function of k_y . Then the carried states among the adiabatic process by increasing the Aharonov-Bohm flux by ϕ_0 in the Laughlin argument is specified by the number of the states localized near each boundary (pairs of particle-hole excitations separated far away by bulk). These are the edge states. Also the continuity of the effective Landau levels as shown in the Fig. 1, implies that this number is the same as that of the number of the Landau levels below the Fermi energy at bulk (far away from the boundaries). Since the number of the filled Landau levels is stable for local perturbation, it is a topological number. We may then consider this relation as an implicit bulk-edge correspondence.

TKNN integer

Here let us consider lattice fermions on a two-dimensional square lattice

$$H = \sum_{i,j} (c_i^\dagger h_{ij} c_j + V_{ij} \hat{n}_i \hat{n}_j), \quad \hat{n}_j = c_j^\dagger c_j$$

where c_j is an annihilation operator of a fermion at the site $j = (m_j, n_j)$ and $\hat{n}_j$ is its number operator. We assume the hopping matrix elements h_{ij} and particle-particle interaction V_{ij} are short-ranged. By identifying the sites j and those at $j + (L_x, 0)$ and $j + (0, L_y)$, $j = 1, \dots, L_x L_y$, the system is a torus of the size $L_x \times L_y$.

We further assume the many-particle ground state is gapped and unique. A typical case is a non-interacting gapped system such as the integer quantum Hall state and topologically non trivial band insulators (Chern insulators (Haldane, 1988)).

It respects a local $U(1)$ gauge invariance

$$UH(\bar{h}_{ij})U^\dagger = H(h_{ij}), \quad U = e^{i\sum_j \Omega_j \hat{n}_j},$$

$$h_{ij} = e^{i(\Omega_i - \Omega_j)} \bar{h}_{ij}$$

where $Uc_j^\dagger U^\dagger = e^{i\Omega_j} c_j^\dagger$. It induces a large gauge transformation, $\Omega_j^g = \theta_x x_j + \theta_y y_j$, $U = U_x U_y$, $U_x = e^{i\theta_x \sum_j x_j \hat{n}_j}$, $U_y = e^{i\theta_y \sum_j y_j \hat{n}_j}$, $x_i = \frac{m_i}{L_x}$ and $y_i = \frac{m_i}{L_y}$.

As for a one-particle state, $|\psi\rangle = \sum_j c_j^\dagger \psi_j |0\rangle$, the Schrödinger equation $H|\psi\rangle = \epsilon|\psi\rangle$ is written as $\sum_j h_{ij} \psi_j = \psi_i \epsilon$. The large gauge transformation implies

$$|\psi\rangle = U|\bar{\psi}\rangle, \quad \psi_j = e^{i\Omega_j^g} \bar{\psi}_j.$$

Assuming $|\bar{\psi}\rangle$ is defined on a torus of the size $L_x L_y$, it satisfies a periodic boundary condition $\bar{\psi}_j = \bar{\psi}_{j+(L_x, 0)} = \bar{\psi}_{j+(0, L_y)}$. It induces a twisted boundary condition for $|\psi\rangle$ as $\psi_j = e^{i\theta_x} \psi_{j+(L_x, 0)} = e^{i\theta_y} \psi_{j+(0, L_y)}$, which can be compared with the effects of the Aharonov-Bohm flux in the Laughlin argument.

We may assume the phase factors $\theta_{x,y} = 2\pi\phi_{x,y}/\phi_0$ as the external vector potential, $\delta\mathbf{A} = \left(\frac{\phi_x}{L_x}, \frac{\phi_y}{L_y}\right) = \frac{\phi_0}{2\pi} \left(\frac{\theta_x}{L_x}, \frac{\theta_y}{L_y}\right)$. Then the current operator in y -direction is given by

$$\hat{I}_y = 2\pi\phi_0^{-1} \partial_y \bar{H}, \quad \bar{H} = H(\bar{h}_{ij}),$$

where $\partial_x = \frac{\partial}{\partial \theta_x}$ ($\alpha = x, y$). Noting the electric field written by the vector potential as $\mathbf{E} = -\partial_\mu \mathbf{A}$, the external electric field in x -direction E_x is expressed by $\delta A_x = -E_x t$, which induces adiabatic time dependence of the system by $\partial_t = -L_x E_x \frac{2\pi}{\phi_0} \partial_x = -V_x \frac{2\pi}{\phi_0} \partial_x$ where $V_x = L_x E_x$ may be understood as a potential difference across the system in x -direction although we assume the system is periodic.

Since the system is gapped, the time-dependent ground state $|G\rangle$ is written by the adiabatic approximation as (Thouless, 1983)

$$|G\rangle = e^{i\Gamma} \left(|g\rangle + i\hbar \sum_{\alpha \neq g} \frac{|\alpha\rangle \langle \alpha| \partial_t g\rangle}{E_\alpha - E_g} \right)$$

where $|\alpha\rangle$ is a many-particle eigenstate of the Hamiltonian $\bar{H}$ as $\bar{H}|\alpha\rangle = |\alpha\rangle E_\alpha$, $\Gamma \in \mathbb{R}$ and $|G(0)\rangle = |g(0)\rangle$ where $|g\rangle$ is a ground state of $\bar{H}$. After a few algebra, one obtains a compact form for the Hall conductance $\sigma_{yx} = I_y/V_x$, $I_y = \langle G | \hat{I}_y | G \rangle$ as

$$\sigma_{yx} = \frac{e^2}{h} \mathcal{C}, \quad \mathcal{C} = \frac{1}{2\pi i} \int_{T^2} d^2 \theta \mathcal{B}_z$$

$$\mathcal{B} = \text{rot } \mathcal{A}, \quad \mathcal{A} = \langle g | \nabla g \rangle,$$

where $\nabla = (\partial_x, \partial_y, \partial_z)$, $T^2 = \{(\theta_x, \theta_y) | 0 \leq \theta_{x,y} \leq 2\pi\}$ is a two dimensional torus and $\mathcal{C}$ is the (first) Chern number of the Berry connection $\mathcal{A}$ (Avron et al., 1983; Kohmoto, 1985). This is the Niu-Thouless-Wu formula (Niu et al., 1985).

As for the non-interacting system, the Chern number $\mathcal{C}^\ell$ is written by that of the one-particle state $|\psi^\ell\rangle$,

$$\mathcal{C} = \sum_{\ell=1}^M \mathcal{C}^\ell, \quad \mathcal{C}^\ell = \frac{1}{2\pi i} \int_{T_{\text{BZ}}^2} d^2 k b_z^\ell(\mathbf{k}),$$

$$\mathbf{b}^\ell(\mathbf{k}) = \text{rot } \mathbf{a}^\ell, \quad \mathbf{a}^\ell(\mathbf{k}) = \langle \psi^\ell(\mathbf{k}) | \nabla_k \psi^\ell(\mathbf{k}) \rangle$$

where $h(\mathbf{k})|\psi^\ell(\mathbf{k})\rangle = |\psi^\ell(\mathbf{k})\rangle \epsilon^\ell(\mathbf{k})$ is a Bloch function of the ℓ -th band and T_{BZ}^2 is the Brillouin zone. We assume the system is a band insulator where the Fermi energy is in the M -th energy gap. This is the celebrated TKNN formula (Thouless et al., 1982; Kohmoto, 1985) written by the Berry connection $\mathbf{a}$ of the Bloch state.² Although explicit calculations of the Chern number are tricky due to the phase ambiguity of the eigenstate (gauge freedom of the Berry connection, $\mathcal{A}$ and $\mathbf{a}$), today, a well-established numerically stable and efficient method is known (Fukui et al., 2005).

Bulk-edge correspondence

Quantum Hall effect to Chern insulators

The TKNN integer is determined without any mention to the boundaries. It implies that the TKNN integer as a topological invariant is a bulk property. According to the Laughlin argument, the Hall conductance is also determined by the consideration of the edge states. Here let us discuss the edge states associated with the TKNN integers, which induces a new topological invariant.

When the system is in a uniform magnetic field, effects of magnetic field are included by the Peierls phase for the hopping h_{ij} . On a square lattice with nearest-neighbor hopping, it is given in the Landau gauge as $h_{j+(1,0),j} = h_{j,j+(1,0)} = -t$ and $h_{j+(0,1),j} = h_{j,j+(0,1)}^* = -te^{i2\pi\phi m}$, ($j = (m, n), t \in \mathbb{R}$) where $2\pi\phi\phi_0$ is a flux per plaquette and $\phi = p/q$ with mutually prime integers p and q . By assuming that $\psi_j = e^{ik_y n} \varphi_m$ (analogs to the discussion of the Landau gauge in the continuum), the one-particle Schrödinger equation, $H|\psi\rangle = |\psi\rangle E$ reduces to the Harper equation, that is a lattice analog of that of the harmonic oscillator,

²Historically the TKNN formula was first discovered based on the linear response theory and extended to the Niu-Thouless-Wu formula (Niu et al., 1985).

$$\varphi_{m+1} + \varphi_{m-1} + 2 \cos(k_y - 2\pi\phi m) \varphi_m = -\epsilon \varphi_m,$$

where $\epsilon = E/t$. Here we consider two cases. The first one is a periodic infinite system (without boundaries). It is for a bulk which gives the TKNN integer. The other is an open-boundary condition, $\varphi_0 = \varphi_{L_x} = 0$, that is for a cylindrical system (Hatsugai, 1993a). This is with edges.

The translation invariance of the Harper equation, $m \rightarrow m + q$, implies the Bloch condition

$$\varphi_{m+q} = \rho \varphi_m.$$

The translation invariance further requires that the state is extended as $\rho(k_x) = e^{ik_x}$, $|\rho| = 1$. They define q energy bands for the spectrum, $\epsilon_\ell(k_x, k_y)$, $\ell = 1, \dots, q$. With boundaries, there appear $g = q - 1$ localized states near the boundaries of the cylinder whose energies μ_j 's ($j = 1, \dots, g$) are in each of the j -th band gap, $\epsilon_\ell(k_x, k_y) \leq \mu_j(k_y) \leq \epsilon_{\ell+1}(k_x, k_y)$, $\ell = 1, \dots, g$ for each k_y , if $L_x = qL'_x$, $L'_x \in \mathbb{N}$ for the Harper equation.³ See Fig. 2 for an example. In this case, the unknown integer in the Laughlin argument is $I_\ell = +1$ ($\ell = 2$), that is a number of the edge states connecting the bands below and above the ℓ -th gap where the Fermi energy lies. It is denoted here by I_ℓ .

As for the Hall conductance, we have two different expressions, $\sigma_{yx}^{\text{bulk}} = \frac{e^2}{h} C$, by bulk due to TKNN and $\sigma_{yx}^{\text{edge}} = \frac{e^2}{h} I_\ell$ for cylindrical system by the Laughlin argument. Then we expect the following physically natural relation which was proved for the system that reduces to the Harper equation (Hatsugai, 1993b)

$$\sigma_{yx}^{\text{bulk}} = \sigma_{yx}^{\text{edge}}. \quad (2)$$

This is the bulk-edge correspondence (Hatsugai, 1993b, 1997). This is a relation for a many-particle state and should be valid not only for the non-interacting system but also for a system with interaction as far as the energy gap of the many particle state does not close. In the non-interacting case, it reduces to the relation for the one-particle states (energy bands) as $\sum_{j=1}^{\ell} C_j = I_\ell$, ($I_0 = 0$). Then by shifting the Fermi energy to the $(\ell-1)$ -th gap, it implies a fundamental formula for a relation for one-particle states (Hatsugai, 1993b) with and without edges

$$C_\ell = I_\ell - I_{\ell-1}. \quad (3)$$

If the Chern number of the band is non-zero, there exist necessarily edge states in the energy gap above or below the energy band for the system with edges. One can predict the existence of the edge states without any calculation with edges. Only a calculation with the Bloch condition is enough. As pointed out later, this formula is applicable not only for quantum Hall systems but also for various systems including classical analogs.

Fig. 2 Schematic energy spectrum of the Harper equation ($q = 3$ and $\ell = 2$ here) as a function of k_y ($L_x = qL'_x$, $L'_x \in \mathbb{N}$). Green areas are energy bands and the lines in the gaps are energies of the edge states. The dotted line is the Fermi energy. The ground state of the left system is (adiabatically) connected to that of the right by the increase of the AB flux by ϕ_0 where the system size is sufficiently large and the hybridization between the right and left edge states is neglected.

³Due to the Laughlin argument, the behavior of the edge states is independent of the details of the boundaries, although their explicit behavior depends on them. Then we can safely discuss its topological behavior for the special parameters.

As for the cylindrical system that reduces to the Harper equation, we may go further topologically. The integer I_j that appears in the Laughlin argument has an independent topological meaning. By the suitable analytical continuation of the energy, $\epsilon \rightarrow z \in \mathbb{C}$, of the Bloch state $\varphi_j(z)$, the Bloch state satisfies the open boundary condition (Hatsugai, 1993a) $\varphi_0(\mu) = 0$ and $\varphi_{L_x}(\mu) = \rho_{L_x}'' = 0$. It implies that the energies of the edge states, μ_j , are zeros of the Bloch function $\varphi_0(z) = 0$ on the extended complex energy surface, that is a genus $g = q - 1$ Riemann surface Σ_g . See Fig. 3 and its caption for the construction and an example, $q = 3$ and $g = 2$. Note that the energy bands are the branch cuts and the energy gaps form loops inside the g holes and the energies of the edge states, μ_j , locate on it.

On the Riemann surface, the positions of the edge states are specified by the location of μ_j . When the edge state is localized near the left(right) boundary of the cylinder, μ_j is on the Riemann surface R_+ (R_-).⁴ This construction of the Riemann surface is for a fixed momentum k_y . Assuming the energy gap is finite for all momentum k_y , each of the Riemann surface is topologically equivalent and identified as Σ_g . The periodicity of the Harper equation for $k_y \in \{0, 2\pi\}$ implies that the edge state energies μ_j form oriented loops denoted by $\mathcal{L}_j$ which define winding numbers $w(\mathcal{L}_j)$. Noting that the position of the edge state on the Riemann surface and that of the real space behavior is related, these winding numbers of the loops $\mathcal{L}_j$ is the unknown integer in the Laughlin argument as $I_j = w(\mathcal{L}_j)$, that is, I_j is a topological number of the edge states.

Although the Chern numbers are gauge independent, that is, independent of the phase of the Bloch state, the gauge fixing of the Bloch state is fundamental. It was first pointed out in ref. Kohmoto (1985) and the general scheme of the gauge fixing is given in ref. Hatsugai (2004). For example, the derivative by parameters is not defined without gauge fixing. Simplest gauge fixing, the convention for the phase of the Bloch state is assuming the q -th component of the Bloch state φ_q to be real positive (Kohmoto, 1985; Hatsugai, 1993b, 2004). However, this convention does not work if $\varphi_q = 0$. This is the gauge singularities. It also implies that the Bloch state also satisfies the condition with edges since $\varphi_q = \rho\varphi_0 = 0$. As shown in the Fig. 3, the loop $\mathcal{L}_j$ of the j -th gap cuts the energy bands (branch cuts) above and below the gap I_j times, that gives gauge singularities of the Berry connections for the j -th and $(j + 1)$ -th bands. It results in the bulk-edge correspondence of the one-particle Chern number Eq. (3) (See ref. Hatsugai, 1993b of the details of the mathematical proof).

Fig. 3 The Riemann surface Σ_g (complex energy surface) of the Bloch function for the Harper equation ($q = 3$ and $g = q - 1 = 2$ here) (Hatsugai, 1993a). (a) Make branch cuts along the energy bands $\epsilon \pm i0$ for the two complex energy planes $R_{\pm}$. (b) Make 2 Riemann spheres by identifying ∞ to a point for each. (c) Glue 2 Riemann spheres by the branch cuts along the red (blue) arrows. (d) The Riemann surface with $g = q - 1$ holes and the zeros of the Bloch function φ_j , μ_j are on the real axes inside the holes. When the edge state is localized near the left (right) boundary of the cylinder, it is on the Riemann surface R_+ (R_-). The g energies of the edge states μ_j form oriented loops associated with change of the momentum k_y : $0 \rightarrow 2\pi$ that wind I_j times around the holes. In this example, $I_1 = +1$ and $I_2 = -1$. The loops $\mathcal{L}_j$ cuts the energy bands B_{j-1} and B_j . These crossings give gauge singularities for each bands, that is the origin of non-zero Chern numbers, $C_1 = -1$, $C_2 = +1$ and $C_3 = -1$ respectively. It establishes the bulk-edge correspondence Eq. (3) (Hatsugai, 1993b).

⁴One may see analogy of the standard discussion of the behavior of the localized state $e_{i\ell x}$ as localized near $x \sim 0$ if $\text{Im } k > 0$ ($x \sim L \gg 1$ if $\text{Im } k < 0$).

Universality of the bulk-edge correspondence

Although physical motivation of the original bulk-edge relation, Eq. (3) is for an integer quantum Hall effect and the proof is for the Harper equation, this relation is applicable for various situations universally where a linear partial differential equation with/without edges. This bulk-edge correspondence has been also focused and discussed from mathematical view points as well (Schulz-Baldes et al., 1999; Kellendonk et al., 2002; Graf and Porta, 2013; Hayashi, 2017).

Discovery of the two-dimensional quantum spin Hall state (Kane and Mele, 2005; Bernevig and Zhang, 2006; König et al., 2007) has triggered the universal use of the bulk-edge correspondence (Kane and Mele, 2005; Qi et al., 2006). It is a layered Haldane model (Haldane, 1988) with spins associated with reversed magnetic fields. The Haldane model breaks the time-reversal symmetry and its gapped ground state is characterized by non-zero TKNN integers (Chern numbers). Today there are various such a class of materials, which is known as the Chern insulators where the edge states associated with the bulk-edge correspondence are observed. The quantum spin Hall state preserves the time-reversal symmetry and their Chern number is zero. They are characterized by the non-zero *spin* Chern numbers (if the spin is conserved) which are not physical observables. What should be observed experimentally are localized *spin* edge states due to the bulk-edge correspondence (Kane and Mele, 2005). This is true even if the spin is not conserved assuming the gap is finite and adiabatically connected to the spin conserved system. The bulk is hidden. Nontrivial topology of the bulk is reflected by the localized degrees of freedom as the edge states. As for topological insulators as three dimensional analog (Fu et al., 2007) of the quantum spin Hall states, the situation is the same. The bulk is hidden and the non-trivial topology of the bulk has never been (at least not easily) measured directly. What can be experimentally measured are surface states governed by the non-trivial topology of the bulk. Angle resolved photoemission spectroscopy (ARPES) experiments have been successfully performed and the surface states predicted by the bulk topology are confirmed in various topological insulators (Moore, 2009; Hasan and Kane, 2010; Qi and Zhang, 2011).

The bulk-edge correspondence governs not only quantum systems but also some of classical analogs. The first such an example is photonic crystal with time-reversal symmetry breaking (Haldane and Raghu, 2008; Wang et al., 2008). Electromagnetic fields in material with periodic structures obeying the Maxwell equation possess energy bands and gaps (photonic gaps). Associated with the time-reversal breaking, there exist topological edge states as one-way going (chiral) modes localized near the system boundaries as a complete analog to that of the integer quantum Hall effect (Halperin, 1982; Hatsugai, 1993a). Such edge states are predicted by the bulk-edge correspondence Eq. (3) (Hatsugai, 1993b) by the non-zero TKNN integers (Chern numbers), although these bulk topological numbers do not have any physical meaning such as the quantized Hall conductance. However, these one-way going edge states are experimentally observed (Wang et al., 2009). The bulk is really hidden and the experimental observables are localized edge states where the bulk-edge correspondence plays a crucial role. This is the fundamental concept of the topological photonics (Ozawa et al., 2019).

Now the classical analogs of the quantum Hall states exist in various fields. Topological mechanics and chiral edge states in classical mechanics (Prodan and Prodan, 2009; Kariyado and Hatsugai, 2015; Huber, 2016). A coupled resonator with time-reversal symmetry breaking also possess chiral edge states (Hafezi et al., 2011). Coupled LC circuits are also described by the bulk-edge correspondence and there exist chiral edge states (Ningyuan et al., 2015) (topological circuit). One of the recent surprises is a topological origin of equatorial waves as chiral edge states associated with finite Chern numbers on earth (Delplace et al., 2017). Well known equatorial waves in geophysics as the Kelvin wave and the Yanai wave are due to the bulk-edge correspondence where the Coriolis force on earth breaks the time-reversal symmetry. The equator is a boundary since the Coriolis force vanishes. The bulk-edge correspondence is further applied for phenomena in different fields. Chiral edge states exist in a spatially coupled macroscopic system described by the evolutionary game theory (Yoshida et al., 2021) and active nematic cells (topological biology) (Yamauchi et al., 2020).

Looking back the discussion up to this point, the topological number of bulk, the Chern number and the TKNN integer are defined by the Berry connection associated with the twisted boundary condition. The twist is originated by the large gauge transformation. This gauge invariance needs not be physical one since it may not be directly related to the physical observables. The fictitious gauge invariance mentioned at the beginning of the section “Laughlin argument and edge states” is written as $\nabla \rightarrow \nabla - i \frac{A_f}{\phi_f}$ where $\phi_f = \frac{h}{e_f}$ is a flux quantum for the fictitious gauge field. It implies the discussion is not restricted to the quantum mechanics since h is hidden. One may use the topological argument by suitable interpretation of the fictitious flux quantum ϕ_f for the (classical) problem as well. This fictitious gauge invariance also allows to use the Laughlin argument which requires edge states governed by the bulk topological number. This conceptually justifies the bulk-edge correspondence for the various non-quantum problems.

Since the conceptual background of the bulk-edge correspondence is a formal analogy to the quantum Hall effects, it is directly applied for two-dimensional problems. When the momentum along the boundary is conserved, one may apply the bulk-edge correspondence for three dimensional problems by slicing the system with a section with fixed such a momentum. The three dimensional quantum Hall effects is a typical and historical example (Halperin, 1987). Assuming the energy gap for fixed momentum, say k_z , one may consider 3-dimensional system as a set of 2-dimensional systems parameterized by k_z . Three dimensional Weyl semi-metals (Wan et al., 2011) can be understood in this way. One may define a Chern number for each section specified by k_z . If this Chern number (section Chern number (Oono et al., 2016)) is non-zero, there exist an edge state due to the bulk-edge correspondence for a system with/without edges specified by k_z . This edge state is the Fermi-arc. The section Chern number may change by changing k_z associated with the gap closing (topological phase transition), which is the Weyl point. It implies that the Fermi-arc are connecting the Weyl points.

Another physical system where the bulk-edge correspondence plays a fundamental role is a one-dimensional topological (adiabatic) pump originally proposed by Thouless (Thouless, 1983) in 1980s. The word, “pump,” implies the system is periodic in time. Assuming the adiabaticity, the time can be considered as a periodic parameter such as a conserved momentum along the cylinder in the Laughlin argument. The momentum k_y in Fig. 2 can be reinterpreted as a time, t , as $k_y \rightarrow 2\pi \frac{t}{T}$ where T is a period of the pump (Hatsugai and Fukui, 2016). Then one may apply the bulk-edge correspondence for a one-dimensional adiabatic pump. After more than several decades studies, this theoretical idea has been experimentally realized in synthetic systems of cold atoms (Nakajima et al., 2016; Lohse et al., 2016). The role of edge state has been discussed motivated by the experimental realization (Hatsugai and Fukui, 2016). It is quite special since the physical observable of the topological pump is a center of mass due to bulk and the edge states cannot be directly measured since gapless nature of the edge states implies that effects of the edge states are hardly observed experimentally. Instead, a topological origin of the topological pump (physical reason for the quantization of the pumped charge) is clear by the argument of the edge state (See ref. Hatsugai and Fukui, 2016). Contrary to the standard topological phases, the edges are hidden and the bulk induces physical observables. This is a unique feature of the topological pump. Still the bulk-edge correspondence plays a fundamental role. As for the topological pump of correlated systems such as interacting fermions and quantum spins, reinterpretation of the time, as a synthetic dimension of the two dimensional topological phases, is impossible. It opens a new area of topological physics. The gap closing of the symmetry protected phases is an origin of the non-trivial topology associated with the symmetry breaking perturbation specified by the time. The bulk-edge correspondence is a key ingredient of the topological pump of the correlated systems (Kuno and Hatsugai, 2020, 2021a,b; Hatsugai and Kuno, 2023).

As discussed, the concept of the bulk-edge correspondence is quite universal. Let us here mention on the effective field theory of the QHE where the gauge invariance of the system with boundaries requires extra boundary action to be gauge invariant as a whole (Wen, 1990). It is a bulk-edge correspondence from a different point, which supports its universality.

Short-range entangled states, symmetry protection and edge states

The bulk-edge correspondence in two-dimensional phenomena as discussed is topologically stable and physically strong against small but finite perturbation unless the energy gap collapses. One may extend the bulk-edge correspondence for wider class of phenomena as generic bulk-edge correspondence (bulk-boundary correspondence) by imposing an additional symmetry restriction. This is the idea of symmetry protection (Hatsugai, 2006; Pollmann et al., 2012; Chen et al., 2013).⁵ A topological order parameter of the symmetry protected topological phases can be a quantized Berry phase (Hatsugai, 2006). Instead of the Chern number that is intrinsically quantized, the Berry phase takes any value in modulo 2π due to the gauge ambiguity (Berry, 1984; Wilczek and Zee, 1984). It has been discussed in momentum space in relation to the polarization (King-Smith and Vanderbilt, 1993). With the symmetry protection, the Berry phase is quantized and works as a topological order parameter (Hatsugai, 2006).

Let us define a short-range entangled state as a set of clusters coupled with each other adiabatically by a short-range interaction without gap closing (Hatsugai, 2006; Kariyado and Hatsugai, 2014) (See Fig. 4). “Adiabatically coupled” implies that the gapped decoupled clusters are coupled to each other without gap closing. In other words, the short-range entangled state is adiabatically

Fig. 4 Adiabatic deformation of a short-range entangled state and edge states. This adiabatic deformation is specified by $\lambda \in [0, 1]$. (a) Many-particle energy spectrum. (b) Cluster decomposition and a system with an edge state (gray region). We assume the system is a collection of the decoupled clusters when $\lambda = 0$.

⁵The symmetry protection by the time-reversal symmetry has been fundamentally important for quantum spin Hall effects and topological insulators (Kane and Mele, 2005).

deformed to a collection of clusters. The former way of the construction is trivial if the coupling is small. This weak coupling ansatz may not be necessary. The interaction between the clusters can be comparable to the one inside. Then the latter way of the construction is a highly non-trivial statement since the distribution of the couplings of the final system does not necessarily reflect the original set of the clusters. It is highly non-trivial task to find the set of clusters for a generic short-range entangled state. An $S = 1/2$ Heisenberg quantum spin chain with alternating exchange interaction due to Hida (Hida, 1992) is a typical example where a set of dimers are coupled with each other by the ferromagnetic Heisenberg interaction J_F . Collection of decoupled dimers is trivially gapped but the system is adiabatically deformed (without gap closing) to the highly non-trivial $S = 1$ Haldane spin chain by taking an infinite coupling limit ($J_F \rightarrow \infty$) where the Berry phase associated with the dimers characterizes the system, which is the Haldane spin chain (Hatsugai, 2006, 2007). On the other hand, one of the examples, that is not short-ranged entangled state, is a non-trivial Chern insulator. Since the Chern number of the decoupled clusters for any kind of boundary twists is vanishing, a system with a finite Chern number is not short-range entangled.

To be specific, let us consider a fermionic system. Quantum spin systems can be also discussed similarly. As for a decoupled limit, we further assume that the filling of the site we focus, say, the site A is rational as $\rho_A = P/Q$, $P, Q \in \mathbb{N}$, $(P, Q) = 1$ where $\rho_j = \langle g_0 | \hat{n}_j | g_0 \rangle$ with a fermion annihilation operator c_j , its number operator $\hat{n}_j = c_j^\dagger c_j$, the many-particle ground state $|g_0\rangle$ of the whole system and the Hamiltonian $H_0(\lambda)$. Let us introduce a local gauge twist θ by $H_A(0) = U_A(\theta) H_0 U_A^\dagger(\theta)$, $U_A = e^{i\theta \hat{n}_A}$ and consider a Berry phase $\gamma_A = -i \int_0^{2\pi} d\theta \langle g | \partial_\theta | g \rangle$ where $H_A(0) |g\rangle = |g\rangle E$. Since $|g\rangle = U_A(\theta) |g_0\rangle$, the Berry phase is fractionally quantized as $\gamma_A = 2\pi \frac{P}{Q}$.

As for the decoupled system, the twists appear in the Hamiltonian H_A as a modified couplings along the red lines in Fig. 4(b) due to the gauge transformation at the site A . Using the same twisted couplings, let us further consider a modified Hamiltonian $H_A(\lambda)$, ($\lambda > 0$). Note that the twist is not gauged out when $\lambda \neq 0$. Then the Berry phase γ_A may take any value and is not quantized in general. Here we further assume the quantization of the Berry phase γ_A for any λ due to some symmetry (*symmetry protection*). Z_2 quantization of the Berry phase for the Bloch function was discussed in the pioneering work of Zak (Zak phase) (Zak, 1989). This Z_2 quantized Berry phase is used for the proposal of topological order parameter for many particle states and quantum spins (Hatsugai, 2006). This symmetry assisted quantization is extended to define Z_Q ($Q = 2, 3, \dots$) Berry phases associated with the Z_Q symmetry (Hatsugai and Maruyama, 2011). Z_Q sub-groups of crystal symmetries are typical examples (See Fig. 5). It includes order 2 unitary/anti-unitary symmetries such as the time-reversal symmetry and the particle hole symmetry of lattice fermions on a bipartite lattice (reduced to the chiral symmetry of one-particle state). We can define Q independent Berry phases, γ_j , $j = 1, \dots, Q$ and impose physical constraints

Fig. 5 Z_Q symmetries of the hyper-pyrochlore lattice with edges/defects. ($Q = d + 1$) Unit vectors on a $(d-1)$ -dimensional sphere, $E_j^{(d)}$, ($j = 1, \dots, Q$) are shown. d independent translation vectors are specified by $e_j^{(d)} = E_j^{(d)} - E_1^{(d)}$, ($j = 1, \dots, d$). Examples for $d = 1$ and $d = 2$ are shown. The black circles are the origins for $d = 1$ and 2. The white circles are uniformly distributed Q points, $E_j^{(d)}$, on the d -dimensional spheres S^d . The colored circles (spheres) of Q species are atomic sites at $\frac{1}{2} E_j^{(d)} + \sum_k n_k E_k^{(d)}$ ($j = 1, \dots, Q$) where $\exists n_k \in \mathbb{Z}$, $\sum_k n_k = 0$. For a suitable shape of the finite system, all atomic sites are connected by the strong bonds (red) except on the boundary (edge/corner/defect) sites (enclosed by thin circles). The system with/without boundaries are Z_Q symmetric. Z_Q symmetry is generated by the shift of the colors, $\sigma: E_j^{(d)} \rightarrow E_{j+1(\text{mod } Q)}^{(d)}$, $\sigma^Q = 1$ (See ref. Hatsugai and Maruyama, 2011 for the definitions of $E_j^{(d)}$ and the details). (a) the dimerized one-dimensional chains ($d = 1$) and (b) breathing Kagome lattice ($d = 2$). The Berry phase of the gapped systems with periodic boundary condition is quantized in $\frac{2\pi}{Q}$. The system with the edges/defects has Q degenerate one particle states (with exponential accuracy as for the distance between the corners) which induce $1/Q$ fractionalization.

$$Z_1 \equiv Z_2 \equiv \cdots \equiv Z_Q, \text{ mod } 2\pi$$

$$0 = Z_1 + \cdots + Z_Q$$

noting that the Berry phase has a 2π ambiguity (Berry, 1984). It implies the Z_Q quantization as ($n \in \mathbb{Z}$)

$$\gamma_A(\lambda) = 0, \quad 2\pi \frac{n}{Q}, \quad (\text{mod } 2\pi).$$

This Z_Q -Berry phase is used as a topological order parameter of the short-range entangled states. If the system is a gray region with boundary as shown in Fig. 4, there exists an edge/corner/defect state at the site A. It is clear that the breaking of the cluster induces the localized edge states (corner states and defect states) (Hatsugai, 2011). If the system is fermionic, existence of a single isolated edge/corner/defect site of the multiple decoupled clusters implies degenerate zero energy one-particle states (zero modes) (Ryu and Hatsugai, 2002). One may consider the other fermionic degrees of the bulk freedom are gapped out away from the zero energy. We assume the zero modes are macroscopically separated such as boundaries of the chain. By the adiabatic inclusion of the interaction between the clusters, the energies of the localized one-particle states may deviate from zero due to the local interaction between the defect and surrounding clusters. Still the Q -fold degeneracy is preserved due to the Z_Q symmetry up to exponentially accuracy as for the system size. It results in the $1/Q$ fractionalization (Jackiw and Rebbi, 1976; Ryu and Hatsugai, 2002) (see Fig. 5).

A typical and historical example is a soliton of polyacetylene (Su et al., 1979; Ryu and Hatsugai, 2002) and the localized spin 1/2 degrees of freedom for the $S = 1$ Haldane chain (Kennedy's triplet (Kennedy, 1990; Pollmann et al., 2012)). Majorana bound states of the anomalous superconductor are also due to the similar idea (Kitaev, 2001). Localized states at corners of 2D and 3D systems of higher-order topological insulators have been focused as edges of edges (Benalcazar et al., 2017; Hashimoto et al., 2017; Schindler et al., 2018; Hayashi, 2018; Ezawa, 2018), which are also symmetry protected localized modes in this class. The Z_Q quantized Berry phases are the topological order parameter of the bulk and the relation between the localized modes are considered as *generalized* bulk-edge correspondence (bulk-boundary correspondence) (Araki et al., 2020; You et al., 2020). The Haldane spin chain is a typical correlated system. We do have similar counterparts in electronic systems as a higher-order topological Mott insulator (Kudo et al., 2019; Otsuka et al., 2021).

Slicing the system with conserved momentum as parameters, that works for the discussion of the Weyl semimetal and Fermi-arc, is also effective for the short-range entangled states in higher dimensions. The Fujita states (Fujita et al., 1996; Hatsugai and Aoki, 2014) of the zigzag boundary of graphene and the Andreev bound states of d -wave superconductors in two-dimensions are understood both as one-dimensional edge states with symmetry protection where conserved momentum as a parameter (Ryu and Hatsugai, 2002). In these examples, experimentally observed local boundary magnetization (Okada and Oshiyama, 2001) and local flux generation (symmetry breaking) of the d -wave superconductor are associated with its symmetry breaking (Ryu and Hatsugai, 2004; Matsumoto and Shiba, 1995).

Conclusion

As for the topological phases, the topological number of the bulk and the edge states as localized gapless modes near the boundaries are intimately related. This is the bulk-edge correspondence, which is established for the quantum Hall effect and its lattice analog. Recently the notion of the bulk-edge correspondence is applied not only for quantum but also for many classical phenomena such as gyromagnetic photonic crystals, equatorial waves on earth and, etc. The gauge invariance associated with charge conservation is fundamental. It justifies the universality of the bulk-edge correspondence.

Abstract

Intensive observables in condensed matter have a microscopic formulation in terms of the electronic ground state. In some cases—such e.g., macroscopic electrical polarization and orbital magnetization—such formulation did not exist until relatively recent times; no expression, computationally implementable within band-structure theory, was available. The turning point occurred in 1993 when the theory of polarization (called “modern” at the time) was founded: it was discovered that polarization is a Berry phase, i.e. a geometrical property of the manifold of the occupied Bloch states. Over the following years a few other observables became accessible to electronic-structure theory and revealed their geometrical nature: most notably orbital magnetization in 2006. The present work thoroughly reviews, in the framework of band-structure theory, all the geometrical observables known to the author at the time of writing. Among the observables addressed, there are common features but also outstanding differences, both formal and phenomenological.

Key points

- Crystalline solids addressed via band-structure theory.
- Bloch geometry in reciprocal space.
- Physical observables having their expression in the ground-state geometry.
- Multiple-valued bulk observables versus single-valued ones.
- Observables related to electrostatics, magnetostatics, and electron transport.

Introduction

Electronic structure has undergone a genuine revolution since the early 1990s, when it was found that macroscopic polarization is a geometric phase (Berry phase) of the electronic wavefunction. The geometrical and/or topological nature of several other ground-state intensive observables was elucidated over the following years; the common archetype of these developments is the celebrated discovery, by Thouless et al. (1982), of the topological nature of the quantum Hall effect.

The present review attempts at a taxonomy of the geometrical/topological observables known so far. We address here only crystalline systems of noninteracting electrons (Hartree-Fock or Kohn-Sham), whose ground state is described in terms of occupied Bloch orbitals, and where all intensive observables obtain for insulators as Brillouin-zone (BZ) integrals, and for metals as

Fermi-volume integrals. An observable is called geometrical when the essential entries of the integrand are $\mathbf{k}$ -derivatives of the Bloch states; more precisely of the *lattice-periodical factors* of the Bloch states. In some special cases a geometrical observable may become topological.

As it will become clear below, the known geometrical observables can be sharply partitioned in two classes, which in the following we will address as class I and II. The formal expression of class I observables has an odd number of $\mathbf{k}$ -derivatives (i.e. one or three) in the integrand, while class II observables are expressed by means of an even number of derivatives (i.e. two). This mathematical difference is at the root of outstanding differences in the physical nature of the observables. For instance observables in class I are defined for insulators only (both formally and phenomenologically), while those in class II may be defined for metals as well.

The overwhelming importance of the number of $\mathbf{k}$ -derivatives entering the geometrical integrand is best illustrated if we address three paradigmatic observables in their “natural” minimal dimension: polarization is one-dimensional (1D), in the sense that it can be defined even for a 1D system; anomalous Hall conductivity requires at least two dimensions, and the so-called “axion” (defined in Section “[Magnetoelectric response and the “axion”](#)”) at least three. When addressed in their minimal dimension, each of these observables obtains as a universal constant times the integral of a dimensionless differential form: 1-form, 2-form, and 3-form, respectively. The coefficients of the 1-form (nowadays called the Berry connection) contains one $\mathbf{k}$ -derivative, the one of the 2-form (nowadays called the Berry curvature) contains two $\mathbf{k}$ -derivatives, and those of the 3-form three $\mathbf{k}$ -derivatives. A basic tenet of differential geometry is that spaces of even and odd dimensions behave quite differently, particularly when considering antisymmetric forms (time-reversal odd in condensed-matter physics). Chern-Simons forms are defined only in odd dimensions, while in dimension $2n$ one may define the n -th Chern form, which is (locally) the generalized curl of the corresponding $2n-1$ Chern-Simons form. The three forms listed above are, in mathematical speak, a Chern-Simons 1-form, a first Chern form, and a Chern-Simons 3-form, respectively. The outstanding qualitative difference between the observables of class I and those of class II are ultimately rooted in the different mathematical features of the corresponding differential forms in odd vs. even dimensions.

In our 3D world the expression of a geometrical observable becomes—as said above—a 3D $\mathbf{k}$ -integral; the number of $\mathbf{k}$ -derivatives in the integrand is, for a given observable, D -independent. As an explicit example, polarization in 3D is proportional to the BZ integral of a 3D Berry connection, where only one $\mathbf{k}$ -derivative appears: Eqs. (7) and (15) below.

As for class I, the only observables known so far are those mentioned above: macroscopic polarization and the axion; the latter is a term which originally appeared as a geometrical contribution to magnetoelectric response, but whose role in electronic-structure theory transcends magnetoelectricity. Both class I observables make sense for insulators only, where they obtain as an integral over the BZ, and both are multivalued, defined modulo 2π in dimensionless units: the modulo 2π ambiguity is fixed only after the termination of a bounded insulating sample is specified. Furthermore in presence of some protecting symmetry only the values zero or π (mod 2π) are allowed: this has clearly a one-to-one mapping to the additive group of the integers modulo 2: the $\mathbb{Z}_2$ group. The observable becomes then a topological index: a $\mathbb{Z}_2$ -odd crystalline insulator cannot be “continuously deformed” into a $\mathbb{Z}_2$ -even one without closing the gap and/or breaking the symmetry protection.

Several ground-state geometrical observables are instead known in class II; differently from class I, all of them are single-valued, and some exist even for metals (both phenomenologically and formally). In the following synoptic table we partition them into time-reversal (T) odd and even; in the former case they can be nonzero only if the solid spontaneously breaks T-symmetry.

<i>Time-reversal odd</i>	<i>Time-reversal even</i>
Anomalous Hall conductivity	Souza-Wilkens-Martin sum rule
Magneto-optical sum rule	??
Orbital magnetization	Drude weight

All these observables will be defined and discussed below in Section “[Class II observables](#)”; here I only comment about the inclusion of a couple of sum rules in the table. A sum rule is a frequency integration, hence not a ground-state property; nonetheless, even if the experiment probes the excitations of the solid, the measured quantity is uniquely determined by its electronic ground state.

In Section “[Bloch geometry](#)” we define the main quantities which formally address the geometry of the occupied Bloch manifold: Bloch projector, Berry connection, Berry curvature, quantum metric. In Section “[Class I observables](#)” we provide the formal expressions for the only known geometrical observables in class I: macroscopic electric polarization and the axion.; we also discuss their topological implication in presence of a protecting symmetry. In Section “[Class II observables](#)” we provide the formal expression and a brief discussion for all the five class-II observables in the synoptic table. For each of them, the geometrical integrand is explicitly displayed twice: once in the standard gauge (the Hamiltonian gauge, defined below) and one gauge-invariant in form. Some general conclusions are drawn in Section “[Conclusion](#)”.

Bloch geometry

The electronic ground-state properties of an independent-electron system are embedded in the one-particle density matrix; for a singlet ground state it equals twice the (spinless) ground state projector $\mathcal{P}$. In a crystalline solid the orbitals assume the Bloch form: $|\psi_{\mathbf{j}\mathbf{k}}\rangle = e^{i\mathbf{k}\cdot\mathbf{r}} |u_{\mathbf{j}\mathbf{k}}\rangle$; here we normalize them to one over the unit cell of volume V_{cell} . The $|u_{\mathbf{j}\mathbf{k}}\rangle$ orbitals are eigenstates of $\mathcal{H}_{\mathbf{k}} = e^{-i\mathbf{k}\cdot\mathbf{r}} \mathcal{H} e^{i\mathbf{k}\cdot\mathbf{r}}$ with eigenvalues $\varepsilon_{\mathbf{j}\mathbf{k}}$. The $|\psi_{\mathbf{j}\mathbf{k}}\rangle$ at different $\mathbf{k}$ values are orthogonal, hence they belong to different Hilbert spaces; one considers instead the quantum geometry of the $|u_{\mathbf{j}\mathbf{k}}\rangle$ state vectors, defined in the Hilbert space of the lattice-periodical functions.

A unitary transformation of the occupied $|u_{jk}\rangle$ among themselves leaves the many-body wavefunction, and all ground-state observables, unchanged. Mixing the $\mathbf{k}$ vectors yields the Wannier functions (in insulators). Here we only consider transformations at fixed $\mathbf{k}$:

$$|u_{jk}\rangle \rightarrow |\tilde{u}_{jk}\rangle = \sum_{\varepsilon_{j'k} < \mu} U_{jj'}(\mathbf{k}) |u_{j'k}\rangle; \quad (1)$$

in mathematical language the unitary matrix $U(\mathbf{k})$ is an element of the nonAbelian gauge group. Even for metals we aim at formula which are gauge-invariant in the sense of Eq. (1). It is customary to dub “Hamiltonian gauge” any gauge where the Hamiltonian eigenstates are *not* unitarily transformed (Vanderbilt, 2018).

The ground-state projector is by definition

$$\mathcal{P} = V_{\text{cell}} \sum_j \int_{\text{BZ}} [d\mathbf{k}] \theta(\mu - \varepsilon_{jk}) |\psi_{jk}\rangle \langle \psi_{jk}|, \quad (2)$$

where the integration is over $[d\mathbf{k}] = d\mathbf{k}/(2\pi)^d$, d is the dimension, and μ is the Fermi level. For $d = 1, 2$ the cell volume V_{cell} must be understood as length and area, respectively; $\mathcal{P}$ is a lattice-periodical operator, commuting with the translation group. We cast $\mathcal{P}$ in terms of gauge-invariant Bloch projectors $\mathcal{P}_{\mathbf{k}}$, defined as follows:

$$\langle \mathbf{r} | \mathcal{P} | \mathbf{r}' \rangle = V_{\text{cell}} \int_{\text{BZ}} [d\mathbf{k}] e^{i\mathbf{k} \cdot (\mathbf{r} - \mathbf{r}')} \langle \mathbf{r} | \mathcal{P}_{\mathbf{k}} | \mathbf{r}' \rangle \quad (3)$$

$$\mathcal{P}_{\mathbf{k}} = \sum_j \theta(\mu - \varepsilon_{jk}) |u_{jk}\rangle \langle u_{jk}|. \quad (4)$$

In order to establish a differential geometry in the space of the parameter $\mathbf{k}$ we choose a gauge which makes the $|u_{jk}\rangle$ smooth (i.e. C^∞) throughout the whole BZ; this is always possible, even in topologically nontrivial materials. This allows us to write the $\mathbf{k}$ -derivatives of $\mathcal{P}_{\mathbf{k}}$:

$$\begin{aligned} \partial_{\mathbf{k}} \mathcal{P}_{\mathbf{k}} = & - \sum_j \delta(\mu - \varepsilon_{jk}) \partial_{\mathbf{k}} \varepsilon_{jk} |u_{jk}\rangle \langle u_{jk}| \\ & + \sum_j \theta(\mu - \varepsilon_{jk}) (|u_{jk}\rangle \langle \partial_{\mathbf{k}} u_{jk}| + |\partial_{\mathbf{k}} u_{jk}\rangle \langle u_{jk}|). \end{aligned} \quad (5)$$

The δ -like singularity at the Fermi surface vanishes in insulators; as for the remaining contributions, they are smooth in insulators and piecewise smooth in metals. We anticipate that the gauge-invariant derivative $\partial_{\mathbf{k}} \mathcal{P}_{\mathbf{k}}$ will be the main entry of class II geometrical observables.

We focus, for the time being, on an insulator with n occupied bands, where

$$\partial_{\mathbf{k}} \mathcal{P}_{\mathbf{k}} = \sum_{j=1}^n (|u_{jk}\rangle \langle \partial_{\mathbf{k}} u_{jk}| + |\partial_{\mathbf{k}} u_{jk}\rangle \langle u_{jk}|). \quad (6)$$

Each of the two terms in parenthesis is gauge-dependent; and in fact the trace $\langle u_{jk} | \partial_{\mathbf{k}} u_{jk} \rangle$, summed over the occupied states and multiplied by i , is the Berry connection entering the theory of polarization, Eq. (15):

$$\mathcal{A}_\alpha(\mathbf{k}) = i \sum_{j=1}^n \langle u_{jk} | \partial_{k_\alpha} u_{jk} \rangle. \quad (7)$$

Its curl is by definition the Berry curvature, and is gauge invariant:

$$\Omega_{\alpha\beta}(\mathbf{k}) = i \sum_{j=1}^n (\langle \partial_{k_\alpha} u_{jk} | \partial_{k_\beta} u_{jk} \rangle - \langle \partial_{k_\beta} u_{jk} | \partial_{k_\alpha} u_{jk} \rangle). \quad (8)$$

In the 2D case the Chern-Gauss-Bonnet theorem states that the dimensionless integral of the curvature (i.e. of the first Chern form) over the BZ (a “compact orientable manifold”) is quantized:

$$\frac{1}{2\pi} \int_{\text{BZ}} d\mathbf{k} \Omega_{xy}(\mathbf{k}) = C_1, \quad (9)$$

where the integer $C_1 \in \mathbb{Z}$ is known as the first Chern number.

In order to establish a metric, one may define a gauge-invariant (squared) distance $D_{\mathbf{k}, \mathbf{k}+\kappa}^2$ between the two sets of n occupied states at $\mathbf{k}$ and $\mathbf{k} + \kappa$, which for infinitesimal κ yields the metric tensor:

$$D_{\mathbf{k}, \mathbf{k}+d\mathbf{k}}^2 = g_{\alpha\beta}(\mathbf{k}) dk_\alpha dk_\beta, \quad (10)$$

where the sum over repeated Cartesian indices is understood (here and throughout). Its expression is

$$g_{\alpha\beta}(\mathbf{k}) = \text{Re} \sum_{j=1}^n \langle \partial_{k_\alpha} u_{jk} | \partial_{k_\beta} u_{jk} \rangle - \sum_{jj'=1}^n \langle \partial_{k_\alpha} u_{jk} | u_{j'k} \rangle \langle u_{j'k} | \partial_{k_\beta} u_{jk} \rangle. \quad (11)$$

This metric made its first appearance in electronic structure in the theory of the maximally localized Wannier functions (Marzari and Vanderbilt, 1997). We notice that the second term in Eq. (11) is real, ergo the metric and the curvature can be cast as the real and imaginary (times -2) parts, respectively, of the metric-curvature tensor

$$F_{\alpha\beta}(\mathbf{k}) = \sum_{j=1}^n \langle \partial_{k_\alpha} u_{jk} | \partial_{k_\beta} u_{jk} \rangle - \sum_{jj'=1}^n \langle \partial_{k_\alpha} u_{jk} | u_{j'k} \rangle \langle u_{j'k} | \partial_{k_\beta} u_{jk} \rangle. \quad (12)$$

The tensor $F_{\alpha\beta}(\mathbf{k})$ is gauge-invariant, but not gauge-invariant *in form*: Eq. (12) is cast in the Hamiltonian gauge. Nonetheless it can be identically recast directly in terms of $\mathcal{A}_{\mathbf{k}}$, ergo as gauge-invariant by inspection:

$$F_{\alpha\beta}(\mathbf{k}) = \text{Tr} \{ \mathcal{A}_{\mathbf{k}} (\partial_{k_\alpha} \mathcal{A}_{\mathbf{k}}) (\partial_{k_\beta} \mathcal{A}_{\mathbf{k}}) \}, \quad (13)$$

where “Tr” indicates the trace over the Hilbert space. We are going to show that an analogous orbital-free expression holds for the geometrical integrands at the root of all the class II observables in the previous table.

Class I observables

Generalities

The observables in class I—defined for insulators only—obtain as the BZ integral of a gauge-dependent integrand, which therefore cannot be *directly* expressed in terms of $\mathcal{A}_{\mathbf{k}}$. It has been anticipated above that, in the case of polarization, the relevant ingredient is one of the two terms in Eq. (6), and not their sum. The BZ-integrated quantity is instead gauge-invariant, although modulo 2π (in dimensionless units); the modulo ambiguity in the corresponding observable is fixed for a bounded sample only after its termination is specified. An essential condition is that even the sample surface is insulating, besides its bulk (Vanderbilt, 2018).

It is expedient to define the nonAbelian Berry connection as

$$\mathcal{A}_{jj',\alpha}(\mathbf{k}) = i \langle u_{jk} | \partial_{k_\alpha} u_{j'k} \rangle, \quad (14)$$

which for any Cartesian coordinate α is an Hermitian matrix in the (occupied) band indices $j j'$. The Abelian Berry connection of the occupied Bloch manifold is the trace of the matrix, Eq. (7): it is clearly a vector function of $\mathbf{k}$, and is the main quantum-mechanical entry in the theory of polarization, Eq. (15) below. The nonAbelian Berry connection is instead needed in the axion theory (Section “*Magnetoelectric response and the “axion”*”).

Polarization

The electrical dipole of a bounded sample is well defined only for a globally neutral system; analogously, the macroscopic polarization of a solid is well defined only after the electronic and nuclear contributions are summed.

The—by now famous—Berry phase theory of polarization, first established by King-Smith and Vanderbilt (1993), yields the macroscopic polarization of a crystalline insulator with n doubly occupied bands as (Vanderbilt, 2018)

$$\mathbf{P} = -2ie \sum_{j=1}^n \int_{\text{BZ}} [d\mathbf{k}] \langle u_{jk} | \partial_{\mathbf{k}} u_{jk} \rangle + \mathbf{P}^{(\text{nuc})}, \quad \mathbf{P}^{(\text{nuc})} = \frac{e}{V_{\text{cell}}} \sum_{\ell} Z_{\ell} \mathbf{R}_{\ell}, \quad (15)$$

where $\mathbf{R}_{\ell}$ are the nuclear coordinates in the unit cell, and Z_{ℓ} the corresponding atomic numbers. The electronic contribution to $\mathbf{P}$ is the BZ integral of the Abelian Berry connection, Eq. (7), times $-2e$. Each of the two contributions separately depends on the (arbitrary) choice of the origin in the unit cell, while their sum is invariant.

A basic tenet of polarization theory holds that—insofar as an unbounded crystalline solid is addressed within band-structure theory—bulk polarization is ambiguous modulo a “quantum”, whose value is $e\mathbf{R}/V_{\text{cell}}$, where $\mathbf{R}$ is any lattice vector (Vanderbilt and King-Smith, 1993). This is kind of obvious looking at the nuclear term in Eq. (15): by adding $\mathbf{R}$ to any $\mathbf{R}_{\ell}$ this term changes by a multiple of the quantum; as for the electronic term, its origin from a Berry phase makes it also arbitrary modulo (twice) the quantum.

In solid state physics it is often legitimate to choose a crystal cell which is a multiple of the primitive cell; this is instead forbidden when addressing $\mathbf{P}$, because the “quantum”—and the multivalued observable—would change. It is therefore worth stressing that, whenever a material is crystalline, a *uniquely defined* lattice is associated with the real sample: the previous statement can even be regarded as an unambiguous definition of “crystallinity”. The actual wavefunction might require a supercell in cases e.g., with correlation, quantum nuclei, finite temperature, chemical disorder (i.e. crystalline alloys). ... Even in these cases the lattice is a mathematical construction uniquely defined (by means of an appropriate average), and $\mathbf{P}$ is a uniquely defined multivalued observable.

Polarization as a topological observable

It is expedient to switch from the three Cartesian components of $\mathbf{P}$ to the three dimensionless quantities $\gamma_s = V_{\text{cell}} \mathbf{G}_s \cdot \mathbf{P}/e$, where $\mathbf{G}_s$ are the fundamental reciprocal-lattice vectors: each of the γ_s is clearly an angle, defined modulo 2π . In presence of inversion

Fig. 1 Two paradigmatic inversion-symmetric lattices in 1d.

(I) symmetry $\mathbf{P} = -\mathbf{P}$, ergo γ_s is either 0 modulo 2π or π modulo 2π : each of the γ_s becomes then a topological $\mathbb{Z}_2$ index, “protected” by I-symmetry (Resta, 2018b).

In 1D the “quantum” is equal to e , and

$$P = \frac{e}{2\pi} \gamma; \quad (16)$$

in the I-symmetric case the two topological classes (i.e. $\mathbb{Z}_2$ -even and $\mathbb{Z}_2$ -odd) are easily illustrated by means of a toy model Hamiltonian.

The top sketch in Fig. 1 refers to an idealized molecular crystal, or to an alternant polymer, like polyacetylene; the bottom sketch refers to an idealized ionic crystal. Both systems are I-symmetric and can be described at the simplest level by an extreme tight-binding model Hamiltonian, whose only parameters are the first-neighbor hoppings t and the onsite energies ε . The top chain has alternating t 's and constant ε ; the bottom chain has constant t and alternating ε 's. At half filling the system is a one-band insulator (except in the non-alternating case); if we consider spinful electrons, charge neutrality requires +1 classical charges on each site for both chains.

It is simple to show that the top chain in Fig. 1 has $P = 0 \bmod e$: it is $\mathbb{Z}_2$ -even; the bottom chain has $P = e/2 \bmod e$, and is $\mathbb{Z}_2$ -odd. It is also a straightforward exercise to show that one cannot “continuously deform” the Hamiltonian (and its ground state) from one case into the other without closing the gap, while conserving I-symmetry. Instead, one could imagine to continuously deform the I-symmetric Hamiltonian from the model one to a realistic one: as a basic tenet of topology, P cannot change insofar the gap does not close.

If—instead of considering unbounded chains within periodic boundary conditions—we address finite chains, i.e. bounded realizations of the same toy-model Hamiltonians, then P (trivially evaluated as the dipole over the length) converges to its topological value in the long-chain limit, independently of the values of the model parameters.

Magnetoelectric response and the “axion”

In insulators where T-symmetry and I-symmetry are both spontaneously broken a magnetic field $\mathbf{B}$ may linearly induce polarization $\mathbf{P}$ and an electric field $\mathbf{E}$ may induce magnetization $\mathbf{M}$:

$$\alpha_{\beta\gamma} = \frac{\partial P_\beta}{\partial B_\gamma} = \frac{\partial M_\gamma}{\partial E_\beta}; \quad (17)$$

the response tensor $\vec{\alpha}$ is dimensionless (in Gaussian units). A simple magnetoelectric crystal is Cr_2O_3 , antiferromagnetic and non-centrosymmetric.

The magnetoelectric tensor $\vec{\alpha}$ is the sum of several terms; here we consider solely the orbital magnetoelectric polarizability, i.e. the clamped-nuclei orbital response only. The tensor obtains from the appropriate Kubo formula and therefore is *not* a ground-state property; nonetheless besides Kubo, an additional purely geometrical term enters the response (Malashevich et al., 2010). This term is a pseudoscalar: it accounts for a component of magnetization parallel to the electric field, or equivalently for a component of polarization parallel to the magnetic field. We are going to focus on this component only, called the “axion”, and indicated with the scalar α . This ground-state geometrical term deserves much attention per se, well beyond its actual contribution to Eq. (17) (Vanderbilt, 2018).

Looking back at Eq. (16), we recognize that P in 1D obtains as a universal constant, times the phase angle γ , and divided by 2π . The electronic contribution to γ is a Berry phase, i.e. the BZ integral of a Chern-Simons 1-form: the 1D Abelian Berry connection, which in turn is the trace of the nonAbelian one, Eq. (14). The axion α has a very similar form:

$$\alpha = \frac{1}{4\pi^2} \frac{e^2}{\hbar c} \theta = \frac{e^2}{\hbar c} \frac{\theta}{2\pi}, \quad (18)$$

where one recognizes the fine-structure constant. The angle θ obtains as the BZ integral of a Chern-Simons 3-form, i.e. of the trace (over the band indices) of an expression whose only entry is the 3D nonAbelian connection, Eq. (14), and where three $\mathbf{k}$ -derivatives appear. Therefore θ can be interpreted as the 3D generalization of the Berry phase in 1D. Both γ and θ are defined modulo 2π , hence both P and α are multivalued observables.

The Chern-Simons 3-form and the angle θ have a simple and elegant expression in the compact mathematicians’ notations, based on wedge products and exterior differentiations. When translated into the prolix notations of electronic-structure theory, θ has the following (rather formidable) expression in terms of the nonAbelian connection matrices $\mathcal{A}_\alpha(\mathbf{k})$, Eq. (14):

$$\theta = -\frac{1}{4\pi} \varepsilon_{\alpha\beta\gamma} \int_{\text{BZ}} d\mathbf{k} \operatorname{tr} \left[\mathcal{A}_\alpha(\mathbf{k}) \partial_{k_\beta} \mathcal{A}_\gamma(\mathbf{k}) - \frac{2i}{3} \mathcal{A}_\alpha(\mathbf{k}) \mathcal{A}_\beta(\mathbf{k}) \mathcal{A}_\gamma(\mathbf{k}) \right], \quad (19)$$

where $\varepsilon_{\alpha\beta\gamma}$ is the antisymmetric tensor, and the symbol “tr” indicates the trace of the matrix (over the band indices), not to be confused with the symbol “Tr” used elsewhere.

In presence of either T-symmetry or I-symmetry $\theta = -\theta$, therefore either $\theta = 0$ or $\theta = \pi$ (modulo 2π): even in this case we have a topological, symmetry-protected, $\mathbb{Z}_2$ index. The T-invariant insulators where $\theta = \pi$ (i.e. $\mathbb{Z}_2$ -odd) are called “strong topological insulators” (Vanderbilt, 2018). The evaluation of Eq. (19) would allow the detection of topological order; first-principle calculations are challenging, though.

We have said above that a nonzero magnetoelectric response requires absence of both T- and I-symmetry, while instead here we are discussing the T-symmetric case. In a topological ($\mathbb{Z}_2$ -odd) insulator two remarkable things happen. (1) All Kubo terms are symmetry forbidden and disappear: the axion is the only surviving term. (2) Because of the same symmetry reasons, the magnetoelectric response of a bounded sample is zero, even though α (a bulk property) is nonzero: ergo the surface must be metallic. And in fact the topologically protected metallic surfaces are experimentally probed in order to detect topological order (Hasan and Kane, 2010; paradigmatic strong topological insulators are Bi_2Se_3 and Bi_2Te_3).

Class II observables

Generalities

The five class II geometrical observables known to the author are reported in the synoptic table displayed in the Introduction. They all obtain from $\mathbf{k}$ -integration (over the BZ in insulators, over the Fermi-volume in metals) of an integrand where two $\mathbf{k}$ -derivatives of the $|u_{jk}\rangle$ Bloch states appear. Loosely speaking, one says that they obtain from integrating a 2-form, even when the integral is in 1D or in 3D.

All class II observables share the following properties, which make them very different from those in class I: the observables are single-valued; the integrand defining them is gauge-invariant; their actual value for a bounded sample does not depend on sample termination; because of this, they admit a “density” and are locally well defined even in inhomogeneous systems (e.g., heterostructures).

The reason behind the tabular arrangement is that the observables on the same row obtain from $\mathbf{k}$ integration of the same geometrical integrand: its imaginary antisymmetric part yields the left side (T-odd observable), while its symmetrical real part yields the right side (T-even observable). The first row is the simplest case: the integrand is the metric-curvature tensor $F_{\alpha\beta}(\mathbf{k})$, Eqs. (12) and (13); for the other rows the integrand is a modification of $F_{\alpha\beta}(\mathbf{k})$, whose entries include the Hamiltonian besides the $|u_{jk}\rangle$ derivatives.

The observables in the left column exist for 2D and 3D systems; those on the right column are well defined even in 1D. At variance with those on the right column, those in the left columns are phenomenologically defined for both insulators and metals, and obtain from integrating the same integrand (over either the BZ or the Fermi volume). This fundamental difference between T-odd and T-even observables owes to the singular Fermi-surface term in Eq. (5), which disappears after anti-symmetrization and therefore does not affect the T-odd observables, while instead it has a huge effect on the T-even observables. The Souza-Wilkens-Martin (SWM) sum rule—defined below—is formally infinite in all metals, and is a material-dependent geometrical ground-state property in insulators. The Drude weight, instead, is trivially zero in all insulators and is a material-dependent property in metals, which admits a geometrical expression.

Time-reversal odd observables

When T-symmetry is absent the spin-up bands are generally different from the spin-down ones. Therefore the expressions of the T-odd observables are given below per spin channel, or equivalently for “spinless electrons”.

Anomalous Hall conductivity

Edwin Hall discovered the eponymous effect in 1879; 2 years later he discovered the anomalous Hall effect in ferromagnetic metals. The latter is, by definition, the Hall effect in absence of a macroscopic $\mathbf{B}$ field. In the normal Hall effect T-symmetry is broken by the applied $\mathbf{B}$ field; in the anomalous one it is spontaneously broken, for instance by the development of ferromagnetic order. The theory of anomalous Hall conductivity in metals has been controversial for many years; since the early 2000s it became clear that, besides extrinsic effects, there is also an intrinsic contribution, which can be expressed as a geometrical property of the occupied Bloch manifold in the pristine crystal (Nagaosa et al., 2010). We address this term only in the following.

The transverse dc conductivity is quantized in insulators, and topological in 2D: this is indeed the Thouless et al. (1982) result, celebrated by the Nobel prize in 2016. Notice however that, in presence of a macroscopic $\mathbf{B}$ field, the present formulation needs to be modified because the Hamiltonian is not lattice-periodical in the usual sense. The topological nature of the observable rules out any extrinsic effect, insofar as the system remains insulating. The metallic case is different: therein extrinsic mechanisms are needed to warrant Ohm’s law; in absence of T-symmetry, extrinsic mechanisms also affect transverse conductivity.

We generalize the Berry curvature, Eq. (8) to include the metallic case as well:

$$\Omega_{\alpha\beta}(\mathbf{k}) = i \sum_j \theta(\mu - \varepsilon_{j\mathbf{k}}) (\langle \partial_{k_\alpha} u_{j\mathbf{k}} | \partial_{k_\beta} u_{j\mathbf{k}} \rangle - \langle \partial_{k_\beta} u_{j\mathbf{k}} | \partial_{k_\alpha} u_{j\mathbf{k}} \rangle); \quad (20)$$

$$= i \text{Tr} \{ \mathcal{P}_{\mathbf{k}} [\partial_{k_\alpha} \mathcal{P}_{\mathbf{k}}, \partial_{k_\beta} \mathcal{P}_{\mathbf{k}}] \}, \quad (21)$$

where the second line owes to Eq. (13). As said above, the Fermi-surface singularity in $\partial_{\mathbf{k}} \mathcal{P}_{\mathbf{k}}$ disappears after anti-symmetrization. The geometrical/topological term in the antisymmetric component of the dc conductivity tensor is

$$\text{Re } \sigma_{\alpha\beta}^{(-)}(0) = -\frac{e^2}{\hbar} \int_{\text{BZ}} [d\mathbf{k}] \Omega_{\alpha\beta}(\mathbf{k}), \quad (22)$$

and it holds as written for either insulators or metals, either in 2D or 3D; in the metallic case the integrand is piecewise continuous.

In the special case of a 2D insulator the anomalous Hall conductivity—as said above—is quantized: in fact it is proportional to the Chern number, Eq. (9):

$$\text{Re } \sigma_{xy}^{(-)}(0) = -\frac{e^2}{\hbar} \int_{\text{BZ}} \frac{d\mathbf{k}}{(2\pi)^2} \Omega_{xy}(\mathbf{k}) = -\frac{e^2}{\hbar} \frac{1}{2\pi} \int_{\text{BZ}} d\mathbf{k} \Omega_{xy}(\mathbf{k}) = -\frac{e^2}{\hbar} C_1; \quad (23)$$

Notice that $\hbar/e^2$ is the natural resistance unit: one klitzing, equal to about $2.6 \cdot 10^4 \Omega$. The possible existence of 2D insulators with nonzero transverse conductivity was pointed out by Haldane in 1988 (co-laureate of the 2016 Nobel prize); actual synthesis of materials which realize the QAHE (quantum anomalous Hall effect) was first achieved in 2013.

Magneto-optical sum rule

Circularly polarized light from a synchrotron source is a very powerful probe for investigating spontaneous T-breaking in the orbital degrees of freedom of a given material, whose great virtue is of being element, structure, and site specific: this kind of spectroscopy goes under the acronym XMCD (X-ray magnetic circular dichroism). An incorrect belief, widespread in the synchrotron-physics community, holds that the XMCD sum-rule (defined below) probes the ground-state orbital magnetization in a given material. It is instead well established that XMCD quantitatively probes T-breaking in a different ground-state observable (Kunes and Oppeneer, 2000; Resta, 2020).

XMCD experiments measure the frequency integral of the imaginary part of the antisymmetric term in the conductivity tensor

$$I_{\alpha\beta} = \text{Im} \int_0^\infty d\omega \sigma_{\alpha\beta}^{(-)}(\omega); \quad (24)$$

or even partial integrals over selected frequency ranges. A kind of fluctuation-dissipation theorem guarantees that $I_{\alpha\beta}$ is a ground-state property of the given T-breaking solid although—as stressed above—the property defined by Eq. (24) does *not* coincide with orbital magnetization. The geometrical ground-state expression for $I_{\alpha\beta}$ in the Hamiltonian gauge is

$$I_{\alpha\beta} = -\frac{\pi e^2}{\hbar^2} \text{Im} \sum_j \int_{\text{BZ}} [d\mathbf{k}] \theta(\mu - \varepsilon_{j\mathbf{k}}) \langle \partial_{k_\alpha} u_{j\mathbf{k}} | (\mathcal{H}_{\mathbf{k}} - \varepsilon_{j\mathbf{k}}) | \partial_{k_\beta} u_{j\mathbf{k}} \rangle, \quad (25)$$

clearly the Fermi-volume (or BZ) integral of an antisymmetric 2-form.

In order to arrive at the equivalent—gauge-invariant in form—expression we define the geometrical tensor field

$$\tilde{G}_{\alpha\beta}(\mathbf{k}) = \text{Tr} \{ (\mathcal{H}_{\mathbf{k}} - \mu) (\partial_{k_\alpha} \mathcal{P}_{\mathbf{k}}) (\partial_{k_\beta} \mathcal{P}_{\mathbf{k}}) \}, \quad (26)$$

whose antisymmetric imaginary part yields the XMCD sum-rule:

$$I_{\alpha\beta} = \frac{\pi e^2}{\hbar^2} \text{Im} \int_{\text{BZ}} [d\mathbf{k}] \tilde{G}_{\alpha\beta}(\mathbf{k}). \quad (27)$$

Orbital magnetization

Magnetization is comprised of two terms: a spin and an orbital one, which can be experimentally resolved. As for the former term, it is trivial within electronic-structure theory: simply proportional to the cell-averaged spin density. The latter term accounts (in common materials) for 5–10% of the total, and is a nontrivial geometrical ground-state property. We address here the orbital term only, indicated with $\mathbf{M}$; the ultimate formula which defines it in a crystalline solid was arrived at in 2006. Its γ -component is, in the Hamiltonian gauge (Ceresoli et al., 2006; Vanderbilt, 2018),

$$M_\gamma = -\frac{e}{\hbar c} \varepsilon_{\gamma\alpha\beta} \text{Im} \sum_j \int_{\text{BZ}} [d\mathbf{k}] \theta(\mu - \varepsilon_{j\mathbf{k}}) \langle \partial_{k_\alpha} u_{j\mathbf{k}} | (2\mu - \mathcal{H}_{\mathbf{k}} - \varepsilon_{j\mathbf{k}}) | \partial_{k_\beta} u_{j\mathbf{k}} \rangle; \quad (28)$$

it is the integral of a gauge-invariant 2-form, clearly different from the one entering the XMCD sum-rule, Eq. (25). The expression holds as it stands in trivial insulators, topological insulators, and metals, in either 2D or 3D.

The insulating case deserves a brief discussion. Suppose we choose an arbitrary μ value within the bulk gap: then Eq. (28) has a term linear in μ . It is easily seen that the μ -derivative of $\mathbf{M}$ is proportional to the BZ integral of the Berry curvature: this is zero in the

trivial case (as one would expect), but nonzero in the topological case. The reason for a μ -dependent $\mathbf{M}$ can be understood by addressing a 2D bounded sample, which is insulating in the bulk but has metallic states at the boundary, topologically protected: these states contribute—according to their filling—to $\mathbf{M}$. Eq. (28) is formulated for an unbounded sample within periodic boundary conditions; nonetheless the μ -dependence of $\mathbf{M}$ therein accounts for the analogous phenomenon in a bounded sample.

In order to display the equivalent expression, gauge-invariant in form, we define the tensor field

$$G_{\alpha\beta}(\mathbf{k}) = \text{Tr}\{|\mathcal{H}_{\mathbf{k}} - \mu|(\partial_{k_\alpha} \mathcal{P}_{\mathbf{k}})(\partial_{k_\beta} \mathcal{P}_{\mathbf{k}})\}, \quad (29)$$

where the operator $|\mathcal{H}_{\mathbf{k}} - \mu|$ is diagonal on the Hamiltonian eigenstates:

$$|\mathcal{H}_{\mathbf{k}} - \mu||u_{j\mathbf{k}}\rangle = |e_{j\mathbf{k}} - \mu||u_{j\mathbf{k}}\rangle. \quad (30)$$

A somewhat lengthy calculation proves that Eq. (28) is equivalent to

$$M_\gamma = -\frac{e}{\hbar c} \varepsilon_{\gamma\alpha\beta} \text{Im} \int_{\text{BZ}} [dk] G_{\alpha\beta}(\mathbf{k}). \quad (31)$$

This elegant gauge-invariant form can be equivalently rewritten (for both insulators and metals) as:

$$\mathbf{M} = \frac{ie}{2\hbar c} \int_{\text{BZ}} [dk] \text{Tr}\{|\mathcal{H}_{\mathbf{k}} - \mu|(\partial_{\mathbf{k}} \mathcal{P}_{\mathbf{k}}) \times (\partial_{\mathbf{k}} \mathcal{P}_{\mathbf{k}})\}. \quad (32)$$

Time-reversal even observables

Longitudinal conductivity

The two geometrical observables on the right side of the synoptic table are both related to longitudinal conductivity: therefore some general considerations are in order. Longitudinal conductivity is by definition the symmetric part of the frequency-dependent conductivity tensor, whose real and imaginary parts are related by causality (Kramers-Kronig relationships). Its general form is

$$\sigma_{\alpha\beta}^{(+)}(\omega) = D_{\alpha\beta} \left[\delta(\omega) + \frac{i}{\pi\omega} \right] + \sigma_{\alpha\beta}^{(\text{regular})}(\omega), \quad (33)$$

where the constant $D_{\alpha\beta}$ goes under the name of Drude weight (also known as charge stiffness); it vanishes in insulators. In the metallic case the singular first term in Eq. (33) accounts for the fact that—in absence of dissipation—a dc electric field induces free acceleration in the many-electron system; the $D_{\alpha\beta}$ value measures its inverse inertia (Resta, 2018a).

Within band-structure theory (i.e. for crystalline systems of noninteracting electrons) the regular term obtains by an interband Kubo formula. It is gapped in both insulators and metals: $\sigma_{\alpha\beta}^{(\text{regular})}(\omega) = 0$ for $\omega < \varepsilon_{\text{gap}}/\hbar$, where ε_{gap} is the minimum direct gap. The Drude weight can instead be regarded as the intraband linear response: see Eq. (41) below.

In the special case of free electrons (i.e. noninteracting electrons in a flat potential) the second term in Eq. (33) vanishes and

$$D_{\alpha\beta} = D_{\text{free}} \delta_{\alpha\beta}, \quad D_{\text{free}} = \frac{\pi e^2 n}{m}, \quad (34)$$

where n is the electron density.

Longitudinal conductivity obeys the f -sum rule:

$$\int_0^\infty d\omega \text{Re} \sigma_{\alpha\beta}(\omega) = \frac{D_{\alpha\beta}}{2} + \int_{\varepsilon_{\text{gap}}/\hbar}^\infty d\omega \text{Re} \sigma_{\alpha\beta}^{(\text{regular})}(\omega) = \frac{D_{\text{free}}}{2} \delta_{\alpha\beta}. \quad (35)$$

Therefore the switching on of the periodic potential has the effect of transferring some spectral weight from the Drude peak into the regular term; as said above, in the case of insulators the Drude peak vanishes and the regular term by itself saturates the f -sum rule.

An important subtlety must be stressed: if the ω -integration includes the ultraviolet and x-ray regions of the spectrum, then the density n in D_{free} must include the core electrons. When the focus is instead on dc transport and optical properties the core contributions to the f -sum rule must be discounted: this happens by construction in a pseudopotential framework.

Souza-Wilkens-Martin sum rule

The so-called gauge-invariant quadratic spread, defined for insulators only, is the BZ-integral of the trace of the metric tensor, Eqs. (11) and (13):

$$\Omega_{\text{I}} = V_{\text{cell}} \sum_{\alpha} \int_{\text{BZ}} [dk] g_{\alpha\alpha}(\mathbf{k}) = V_{\text{cell}} \sum_{\alpha} \int_{\text{BZ}} [dk] \text{Re} \mathcal{F}_{\alpha\alpha}(\mathbf{k}). \quad (36)$$

Since the diagonal elements are real, the “Re” will be omitted in the following.

The quantity Ω_{I} entered electronic-structure theory as a formal quantity in the theory of maximally localized Wannier functions (Marzari and Vanderbilt, 1997; Marzari et al., 2012; Vanderbilt, 2018). Such quantity was not defined originally by means of a physical observable; nonetheless any gauge-invariant property of the electronic ground state corresponds—at least in principle—to

a measurable quantity, and therefore some experiment should ideally yield the Ω_I value. It was discovered by Souza et al. (2000) that Ω_I is proportional to a sum rule for longitudinal conductivity.

The key SWM integral is

$$I^{(\text{SWM})} = \int_0^\infty \frac{d\omega}{\omega} \sum_\alpha \sigma_{\alpha\alpha}^{(+)}(\omega), \quad (37)$$

and was introduced as the main discriminant between metals and insulators. The integral was mostly aimed at nontrivial insulators, including e.g., Anderson insulators, Mott insulators, and more; $I^{(\text{SWM})}$ has the virtue of being divergent in all metals and convergent to a finite value in all insulators (Souza et al., 2000; Resta, 2018c). In the present review we limit ourselves throughout to band-structure theory, i.e. the special case of crystalline systems of noninteracting electrons: therein the metallic divergence is obvious from the first (Drude) term in Eq. (33).

In the insulating case $I^{(\text{SWM})}$ is instead finite and material-dependent; a kind of fluctuation-dissipation theorem relates it indeed to Ω_I . The SWM sum rule reads

$$\frac{\hbar}{\pi e^2} \int_{\epsilon_{\text{gap}}/\hbar}^\infty \frac{d\omega}{\omega} \sum_\alpha \sigma_{\alpha\alpha}^{(+)}(\omega) = \frac{\Omega_I}{V_{\text{cell}}} = \sum_\alpha \int_{\text{BZ}} [dk] \mathcal{F}_{\alpha\alpha}(\mathbf{k}), \quad (38)$$

where $\mathcal{F}_{\alpha\alpha}(\mathbf{k})$ is a diagonal element of the metric-curvature tensor, Eqs. (12) and (13).

Drude weight

For a crystalline metal with double band occupancy the Drude weight obtains as a the Fermi-volume integral (Resta, 2018a):

$$D_{\alpha\beta} = 2\pi e^2 \sum_j \int_{\text{BZ}} [dk] \theta(\mu - \epsilon_{j\mathbf{k}}) m_{j,\alpha\beta}^{-1}(\mathbf{k}), \quad (39)$$

where the effective inverse mass tensor of band j is

$$m_{j,\alpha\beta}^{-1}(\mathbf{k}) = \frac{1}{\hbar^2} \frac{\partial^2 \epsilon_{j\mathbf{k}}}{\partial k_\alpha \partial k_\beta}. \quad (40)$$

Only partially occupied bands contribute to $D_{\alpha\beta}$; in insulators Eq. (39) vanishes altogether.

Eq. (39) can be equivalently expressed as a Fermi-surface integral, by means of an integration by parts: it acquires then the meaning of an “intradband” term:

$$D_{\alpha\beta} = -2\pi e^2 \sum_j \int_{\text{BZ}} [dk] f'(\epsilon_{j\mathbf{k}}) v_{j\alpha}(\mathbf{k}) v_{j\beta}(\mathbf{k}), \quad v_{j\alpha}(\mathbf{k}) = \frac{1}{\hbar} \frac{\partial \epsilon_{j\mathbf{k}}}{\partial k_\alpha}, \quad (41)$$

where at zero temperature the Fermi occupation function is $f(\epsilon) = \theta(\mu - \epsilon)$. The formula as given is for a simple Fermi surface; in general there may be multiple bands that cross the Fermi level and Fermi surfaces having complex topology, for example including disconnected sections. Actual integration by parts requires then some care.

The Fermi-surface expression shows explicit agreement with the spirit of Landau’s Fermi-liquid theory, which holds that charge transport in metals involves only quasiparticles with energies within $k_B T$ of the Fermi level. Indeed, Eq. (41) can be alternatively derived in a purely semiclassical framework (Ashcroft and Mermin, 1976).

Both Eqs. (39) and (41) do not look “geometrical”; nonetheless there is an alternative and very meaningful expression equivalent to Eq. (40), where the deviation of $m_{j,\alpha\beta}^{-1}(\mathbf{k})$ from its free-electron value appears as a geometrical term in reciprocal space. We remind that the orbitals $|u_{j\mathbf{k}}\rangle$ are eigenstates of $\mathcal{H}_{\mathbf{k}} = e^{-i\mathbf{k}\cdot\mathbf{r}} \mathcal{H} e^{i\mathbf{k}\cdot\mathbf{r}}$, hence the identity $\langle u_{j\mathbf{k}} | (\mathcal{H}_{\mathbf{k}} - \epsilon_{j\mathbf{k}}) | u_{j\mathbf{k}} \rangle \equiv 0$ holds. Taking two derivatives, one arrives at

$$m_{j,\alpha\beta}^{-1}(\mathbf{k}) = \frac{1}{m} \delta_{\alpha\beta} - \frac{2}{\hbar^2} \text{Re} \langle \partial_{k_\alpha} u_{j\mathbf{k}} | (\mathcal{H}_{\mathbf{k}} - \epsilon_{j\mathbf{k}}) | \partial_{k_\beta} u_{j\mathbf{k}} \rangle, \quad (42)$$

$$D_{\alpha\beta} = \frac{\pi e^2 n}{m} \delta_{\alpha\beta} - \frac{4\pi e^2}{\hbar^2} \sum_j \int_{\text{BZ}} [dk] \theta(\mu - \epsilon_{j\mathbf{k}}) \text{Re} \langle \partial_{k_\alpha} u_{j\mathbf{k}} | (\mathcal{H}_{\mathbf{k}} - \epsilon_{j\mathbf{k}}) | \partial_{k_\beta} u_{j\mathbf{k}} \rangle; \quad (43)$$

therein the first term on the r.h.s. is the free-electron Drude weight $D_{\text{free}} \delta_{\alpha\beta}$, while the second one is a geometrical correction due to the periodic potential; for free electrons the $|u_{j\mathbf{k}}\rangle$ are $\mathbf{k}$ -independent, ergo the correction vanishes.

Eq. (43) is formulated in the Hamiltonian gauge. In order to cast it as gauge-invariant in form we remind that $\partial_{\mathbf{k}} \mathcal{P}_{\mathbf{k}}$, Eq. (5) comprises a singular Fermi-surface term, which needs to be discounted here. We therefore define the regular term in Eq. (5) as

$$\partial_{\mathbf{k}}^{(\text{r})} \mathcal{P}_{\mathbf{k}} = \sum_j \theta(\mu - \epsilon_{j\mathbf{k}}) (|u_{j\mathbf{k}}\rangle \langle \partial_{\mathbf{k}} u_{j\mathbf{k}}| + |\partial_{\mathbf{k}} u_{j\mathbf{k}}\rangle \langle u_{j\mathbf{k}}|),$$

and we notice that—owing to anti-symmetrization—the difference between $\partial_{\mathbf{k}}^{(\text{r})} \mathcal{P}_{\mathbf{k}}$ and $\partial_{\mathbf{k}} \mathcal{P}_{\mathbf{k}}$ is irrelevant in all the previous expressions for the T-odd observables. It is expedient to redefine the gauge-invariant tensor field $G_{\alpha\beta}(\mathbf{k})$, Eq. (29), as

$$G_{\alpha\beta}(\mathbf{k}) = \text{Tr} \left\{ \left[\mathcal{H}_{\mathbf{k}} - \mu \right] \left(\partial_{k_{\alpha}}^{(r)} \mathcal{P}_{\mathbf{k}} \right) \left(\partial_{k_{\beta}}^{(r)} \mathcal{P}_{\mathbf{k}} \right) \right\}, \quad (44)$$

whose imaginary antisymmetric part defines the orbital magnetization, Eqs. (31) and (32). A somewhat lengthy calculation shows that Eq. (43) can be identically recast as

$$D_{\alpha\beta} = D_{\text{free}} \delta_{\alpha\beta} - \frac{4\pi e^2}{\hbar^2} \int_{\text{BZ}} [dk] \text{Re } G_{\alpha\beta}(\mathbf{k}). \quad (45)$$

Conclusion

We have provided here the quantum-mechanical formulations for seven ground-state observables which enter very different physical phenomena: three of them belong to electrostatics/magnetostatics (polarization, orbital magnetization, magnetoelectric coupling); two concern dc conductivity (anomalous Hall conductivity and Drude weight); and two are conductivity sum rules. Despite being so different from the phenomenology viewpoint, all these observables are related by the common fil rouge of Bloch geometry.

For all these seven observables the microscopic formal expression is geometrical, although—as stressed throughout—such expressions are sharply partitioned in two classes, called here I and II. Such formal difference has a strong qualitative implication on phenomenological features of the corresponding observables, in particular about their multiple-valued versus single-valued bulk nature.

Macroscopic polarization $\mathbf{P}$ and orbital magnetization $\mathbf{M}$ are two paradigmatic observables which deserve some further comments. When a bounded sample is addressed, the definitions of the two observables are very similar: $\mathbf{P}$ is the dipole over the volume, $\mathbf{M}$ is the orbital moment over the volume (large-sample limit thereof). Furthermore the formal expression for the dipole (of the microscopic charge density) and for the orbital moment (of the microscopic current density) are also very similar. The corresponding expressions for unbounded samples within band-structure theory became available in 1993 for $\mathbf{P}$ and in 2006 for $\mathbf{M}$. Contrary to some expectations, it was immediately realized that geometry-wise the two observables are extremely different: according to the present partition $\mathbf{P}$ is in class I, $\mathbf{M}$ in class II. We have emphasized here the profound reason for such difference: at bare bones $\mathbf{P}$ is a one-dimensional phenomenon while $\mathbf{M}$ is a two-dimensional one; at the root of their difference is algebraic geometry, which displays very different features in odd vs. even dimensions.

Observables in class I are defined for insulators only, and the geometrical integrands entering them are gauge-dependent. Only the BZ integral is gauge-invariant, although modulo 2π (in dimensionless units). The observables in class II may be defined for metals as well, and the geometrical integrand entering them is gauge-invariant. For each of the five class II observables a double expression is provided here: the first one is given in the Hamiltonian gauge (as in most of the existing literature); the second one is gauge-invariant by inspection.

The presence/absence of a Fermi surface in the metallic/insulating band structure has an overwhelming effect on class II observables: when they are further partitioned in T-odd and T-even ones (left and right column in the synoptic table) a general trend becomes perspicuous.

The three known T-odd observables obtain in either metals or insulators by integrating the same geometrical integrand (a 2-form) on either the Fermi volume or on the BZ; the presence of a Fermi surface plays essentially no role, and this owes in turn to the fact that the 2-forms are antisymmetric in the T-odd cases. Instead in the T-even cases the geometrical integrands are symmetrical and the presence/absence of a Fermi surface has outstanding consequences: the SWM sum rule defines a material-dependent ground-state property for insulators only, while oppositely the Drude weight defines a material-dependent ground-state property for metals only.

Finally, some considerations on the special cases where a geometrical observable may become topological: even in this respect the difference between class I and class II observables is extreme. In class I the observable becomes topological only when “protected” by a given symmetry (either T or I), in which case the invariant is a two-valued index, i.e. $\mathbb{Z}_2$. In class II, instead, only one of the observables dealt with above becomes topological: anomalous Hall conductivity in a 2D insulator. It does not require any protecting symmetry; quite on the contrary, it requires T-symmetry to be absent. The topological invariant is a Chern number, i.e. a $\mathbb{Z}$ index (not $\mathbb{Z}_2$).

Abstract

This chapter describes topological (Dirac and Weyl) semimetals from the viewpoint of their observable electromagnetic response. We argue that this response may be represented by topological terms with unquantized (non-integer) coefficients and make a connection with the Luttinger's theorem, which relates the size of the Fermi surface of an ordinary metal to the number of electrons per unit cell. We discuss observable transport phenomena, associated with this topological response.

Key points

- Topological semimetals are intermediate phases between insulators with different electronic structure topology.
- Topological response of Dirac and Weyl topological semimetals may be viewed as a consequence of the chiral anomaly.
- Observable manifestations are intrinsic anomalous Hall effect with a noninteger Hall conductance in units of e^2/h per atomic plane, negative longitudinal magnetoresistance, scale-dependent quasiballistic transport and extra low-frequency peak in the optical conductivity.

Introduction

Solid crystalline materials are typically categorized as either metals or insulators. Metals have a finite conductivity in the limit of zero temperature, while in insulators the conductivity tends to zero in this limit. The existence of metals and insulators is a fundamental consequence of quantum mechanics and is one of the basic macroscopic quantum phenomena. Whether a given material is a metal or an insulator is determined by a single parameter: the number of valence electrons per unit cell per spin, or filling, denoted as ν henceforth. If ν is not an integer, the material is a metal (unless electron-electron interactions are so strong that a Mott insulator state is formed). The main characteristic of a conventional metal is the existence of a Fermi surface: a surface in the crystal momentum space, separating filled and empty states, whose volume is directly proportional to the fractional part of the filling, a statement known as the Luttinger's theorem. On the other hand, if ν is an integer, the material is either an insulator or a compensated semimetal, which has a number of electron and hole pockets, whose total volume in momentum space, weighted by the sign of the charge carrier (i.e. negative for electrons and positive for holes), sums up to zero. Since the existence of a compensated semimetal is not required by the Luttinger's theorem, it may be viewed as accidental, in the sense that it may be deformed to an insulator without changing ν . We may then say that a noninteger ν always corresponds to a metal, while integer ν always means an insulator.

This simple picture, which has been around for many decades, was significantly enriched and modified by the recent developments in understanding the role of topology in condensed matter physics. In particular, it has been understood that a (semi)metallic state may arise for topological reasons in situations when the Luttinger parameter is an integer, which would normally correspond to an insulator. The simplest example of this are the metallic surface states of topological insulators, which arise inevitably as a consequence of the bulk insulator electronic structure topology. Topological semimetals may also exist in stand-alone bulk systems, most naturally in three spatial dimensions (3D). Just as ordinary metals may be viewed as intermediate phases between two band insulators, corresponding to different integer values of ν , topological semimetals arise as intermediate phases between insulators with different electronic structure topology at a fixed integer value of ν . For example, a magnetic Weyl semimetal is an intermediate phase between an ordinary 3D insulator and an integer quantum Hall insulator with the Hall conductance of e^2/h per atomic plane. A time-reversal (TR) invariant Weyl semimetal is an intermediate phase between an ordinary insulator and a 3D TR-invariant topological insulator (TI), which has an odd number of two-dimensional (2D) Dirac cone surface

[☆]Change History: July 2022. AA Burkov updated the chapter.

states. A (type-I) Dirac semimetal is an intermediate phase between an ordinary insulator and a weak topological crystalline insulator, protected by a combination of TR, inversion, and crystal rotation symmetries. A nodal line semimetal is an intermediate phase between an ordinary insulator and a topological crystalline insulator, protected by mirror symmetry.

Just as an ordinary metal may be characterized by a fractional value of the filling parameter ν , which determines the size of its Fermi surface, topological semimetals may be characterized by topological invariants, which, although not integer, not quantized, and continuously tunable, are otherwise robust to interactions and disorder. Integer values of these invariants correspond to insulators, while fractional values correspond to topological semimetal phases, intermediate between the insulators. In the simplest case of the magnetic Weyl semimetal, this tunable invariant is the Hall conductance per atomic plane in units of e^2/h . Any noninteger value of this invariant requires Weyl band-touching nodes to be present when the Luttinger parameter ν is an integer (otherwise the Hall conductance can take any value due to the contribution of the Fermi surface). In other types of topological semimetals, the invariants are more subtle, but the idea remains the same: a noninteger value of the invariant requires gapless band-touching points or lines to be present.

Magnetic Weyl semimetal

This section explains the connection between unquantized topological invariants and the existence of gapless band-touching points in the Brillouin zone (BZ) on the simplest example of a topological semimetal: a magnetic Weyl semimetal with only a pair (the minimal number) of band-touching nodes. Such a Weyl semimetal arises as an intermediate phase between a quantum anomalous Hall and an ordinary insulator in 3D.

A 3D quantum anomalous Hall insulator may be obtained by making a stack of 2D quantum Hall insulators. 2D quantum anomalous Hall effect (QAHE) arises naturally in a very thin film of a 3D TI material, doped with magnetic impurities. A 3D TR-invariant TI is a bulk insulator with nontrivial electronic structure topology, which leads to gapless metallic surface states, described by a 2D massless Dirac Hamiltonian of the general form

$$H = \hbar v_F (\hat{z} \times \sigma) \cdot \mathbf{k}, \quad (1)$$

where σ is the spin degree of freedom, v_F is the Fermi velocity, and $\hat{z}$ is the normal to the surface. The gaplessness of the spectrum of Eq. (1) is protected by TR symmetry, which prohibits the “mass” term in the 2D Dirac Hamiltonian. If time reversal symmetry is violated, which may be accomplished by doping the surface with magnetic impurities, the “mass” term will be allowed and a gap in the 2D Dirac surface state dispersion will be opened.

A thin film of magnetically-doped 3D TI, shown in Fig. 1, may be modeled by focusing only on the low-energy degrees of freedom, which are simply the 2D Dirac surface states of Eq. (1) on the top and bottom surfaces of the film. The corresponding Hamiltonian reads

$$H = \hbar v_F \tau^z (\hat{z} \times \sigma) \cdot \mathbf{k} + \Delta_S \tau^x + b \sigma^z. \quad (2)$$

Here the eigenvalues of τ^z refer to the top or bottom surface degree of freedom, Δ_S is the probability amplitude for tunneling between the top and bottom surfaces of the film, and b is the exchange spin-splitting, which arises due to the presence of magnetized impurities. Note that $b\sigma^z$ acts as a “mass term” for the individual 2D Dirac surface states, as mentioned above. A unitary transformation brings this to the form

$$H = \hbar v_F (\hat{z} \times \sigma) \cdot \mathbf{k} + (\Delta_S \tau^x + b) \sigma^z, \quad (3)$$

which may be further brought to a block-diagonal form by diagonalizing the $\Delta_S \tau^x$ matrix

$$H_r = \hbar v_F (\hat{z} \times \sigma) \cdot \mathbf{k} + (b + r \Delta_S) \sigma^z, \quad (4)$$

Fig. 1 Thin film of magnetically doped 3D TI. Δ_S is the tunneling amplitude between the top and bottom 2D Dirac surface states and b is the spin splitting due to magnetized impurities. When $b > \Delta_S$, the film is a quantum anomalous Hall insulator with $\sigma_{xy} = e^2/h$. When $b < \Delta_S$, it is an ordinary insulator with zero Hall conductivity.

where $r = \pm$. Each of the 2×2 blocks of Eq. (4) is the Hamiltonian of a 2D Dirac fermion with a “mass” $m_r = b + r\Delta_S$. The 2D Dirac fermion possesses an important property, which is known as the “parity anomaly.” In our context this means that $H_{\pm}$ is associated with a Hall conductivity

$$\sigma_{xy}^r = \frac{e^2}{2h} \text{sign}(m_r), \quad (5)$$

when the Fermi energy is in the gap between the positive and negative energy bands, obtained by diagonalizing H_r

$$\varepsilon_{rs}(\mathbf{k}) = s\sqrt{\hbar^2 v_F^2 \mathbf{k}^2 + m_r^2}, \quad (6)$$

with $s = \pm$. This implies that this system exhibits a quantum Hall plateau transition from $\sigma_{xy} = 0$ to $\sigma_{xy} = e^2/h$ as the ratio of b/Δ_S is varied and taking both b and Δ_S to be positive for concreteness. In other words, in 2D there exists a direct transition between a topological insulator with $\sigma_{xy} = e^2/h$ and a normal insulator with $\sigma_{xy} = 0$. The critical point between the two is described by a massless 2D Dirac Hamiltonian.

Suppose we now make a stack of such 2D layers, exhibiting QAHE, as shown in Fig. 2. Let individual layers be separated by insulating spacers, such that the amplitude for tunneling between the adjacent surfaces of neighboring QAHE layers is Δ_D , which we will also take to be positive. The Hamiltonian, that describes this system, takes the form.

$$H = \hbar v_F \tau^z (\hat{z} \times \boldsymbol{\sigma}) \cdot \mathbf{k} + [\Delta_S + \Delta_D \cos(k_z d)] \tau^x - \Delta_D \sin(k_z d) \tau^y + b \sigma^z, \quad (7)$$

where d is the period of the resulting superlattice heterostructure in the z -direction. Making the same unitary transformation as above and partially diagonalizing the resulting Hamiltonian, we obtain

$$H_r = \hbar v_F (\hat{z} \times \boldsymbol{\sigma}) \cdot \mathbf{k} + m_r(k_z) \sigma^z, \quad (8)$$

where $m_r(k_z) = b + r\sqrt{\Delta_S^2 + \Delta_D^2 + 2\Delta_S\Delta_D \cos(k_z d)} \equiv b + r\Delta(k_z)$. Now we see that the quantum Hall plateau transition we discussed before as a function of b/Δ_S , may now happen in momentum space as k_z is swept through the BZ. Indeed $m_{\pm}(k_z)$ will change sign at $k_z^{\pm} = \pi/d \pm Q$, where

$$Q = \frac{1}{d} \arccos\left(\frac{\Delta_S^2 + \Delta_D^2 - b^2}{2\Delta_S\Delta_D}\right). \quad (9)$$

At $\mathbf{k} = (0, 0, k_z^{\pm})$, the two nondegenerate bands, corresponding to the eigenvalue $r = -$ touch each other, i.e. these are locations of two Weyl nodes, see Fig. 3.

The nodes exist as long the spin splitting b is in the interval between two critical values $b_{c1} < b < b_{c2}$, where $b_{c1} = |\Delta_S - \Delta_D|$ and $b_{c2} = \Delta_S + \Delta_D$. When $b < b_{c1}$ the system is an ordinary insulator with $\sigma_{xy} = 0$, while when $b > b_{c2}$ it is a 3D quantum anomalous Hall insulator with $\sigma_{xy} = e^2/hd$. In between the heterostructure is in the intermediate Weyl semimetal phase with

$$\sigma_{xy} = \frac{2Q}{2\pi} \frac{e^2}{h}, \quad (10)$$

which depends only on the distance between the Weyl nodes in momentum space and varies continuously between 0 and e^2/hd . Thus, unlike in 2D, in 3D a direct transition between a TI with nonzero quantized Hall conductivity and a normal insulator with zero Hall conductivity does not exist. The transition instead proceeds through an intermediate gapless Weyl semimetal phase. The system, described above, constitutes the simplest potential realization of a topological semimetal. Most of the properties of Weyl and Dirac semimetals may be understood by studying this system.

Fig. 2 Coupled-layer construction of an elementary Weyl semimetal. Magnetically-doped TI layers are coupled through insulating spacers. The tunneling amplitude between neighboring TI layers is Δ_D .

Fig. 3 (A) Electronic structure of the simplest Weyl semimetal, with two nodes of opposite chirality, separated by a distance of $2Q$ along the z -axis in momentum space. (B) The corresponding anomalous Hall conductivity as a function of b/Δ_S , showing a broadened plateau transition. Weyl semimetal is an intermediate gapless phase between the quantum anomalous Hall and ordinary insulators.

Chiral anomaly

This section describes basics of the topological response of Weyl and other point node semimetals. This response may be viewed as a consequence of the chiral anomaly, a phenomenon, originally discovered in the particle physics context by Adler, Bell and Jackiw. To understand the connection to the chiral anomaly, let us note that the Hall conductivity of a magnetic Weyl semimetal Eq. (10) may be expressed as the following contribution to the imaginary-time action of the electromagnetic field

$$S = i \frac{2Q}{4\pi} \frac{e}{\Phi_0} \int d^3r \epsilon_{\alpha\beta\gamma} A_\alpha \partial_\beta A_\gamma, \quad (11)$$

where A_μ is the gauge potential of the electromagnetic field, $\Phi_0 = h/e$ is the magnetic flux quantum, and the Hall conductivity is obtained by varying S with respect to A_x

$$j_x = -\frac{\delta S}{\delta A_x} = \frac{2Q}{2\pi} \frac{e^2}{h} E_y. \quad (12)$$

To make a connection with the chiral anomaly, we need to first remind ourselves of some basic notions of the crystal elasticity theory. A perfect 3D crystal may be described in terms of three families of crystal planes, defined by the relation

$$\theta^i(\mathbf{R}, t) = \mathbf{b}^i \cdot \mathbf{R} = 2\pi n^i, \quad (13)$$

where $i = 1, 2, 3$, $\mathbf{R}$ are the Bravais lattice vectors, $\mathbf{b}^i$ are the three primitive reciprocal lattice vectors and n^i are integers. In a distorted crystal, $\theta^i(\mathbf{R}, t) = 2\pi n^i$ continues to hold, where $\tilde{\mathbf{R}}$ are the actual lattice site positions, but $\partial_j \theta^i = b_j^i$ no longer holds. Instead $\partial_j \theta^i$ may be viewed as components of local coordinate basis vectors of the reciprocal space in a distorted crystal. It is then useful to view

$$e_\mu^i = \frac{1}{2\pi} \partial_\mu \theta^i, \quad (14)$$

which may have temporal in addition to spatial components, as crystal translational symmetry “gauge fields.” In a crystal without dislocations, $de^i = \frac{1}{2} (\partial_\mu e_\nu^i - \partial_\nu e_\mu^i) dx^\mu dx^\nu = 0$, as follows from Eq. (14). If a dislocation with a Burgers vector along $\mathbf{b}^i$ is present, the integral around a loop, enclosing the dislocation line, is $\oint e^i = 1$. Everywhere outside of the dislocation line, however, we may still take $de^i = 0$, which will be assumed henceforth.

The point of this exercise in the crystal elasticity theory, is that Eq. (11) may now be rewritten as

$$\begin{aligned} S &= i \frac{1}{2} \frac{e}{\Phi_0} \frac{2Q}{2\pi/d} \int d^3r \epsilon_{\mu\nu\alpha\beta} e_\mu^i A_\nu \partial_\alpha A_\beta \\ &= i \frac{\lambda}{2} \frac{e}{\Phi_0} \int e^i \wedge \mathbf{A} \wedge d\mathbf{A}. \end{aligned} \quad (15)$$

Here $\lambda = 2Q/(2\pi/d)$ is the dimensionless magnitude of the separation between the Weyl nodes in units of the reciprocal lattice vector. This looks like a standard topological term, since it involves only gauge fields and a universal coefficient, except for the fact that the coefficient is not quantized, since λ is not an integer and is continuously tunable. This is exactly analogous to the noninteger value of the Luttinger filling parameter ν in metals, which requires Fermi surface of gapless modes to be present. In a Weyl semimetal ν is integer, but a noninteger value of the parameter λ still requires gapless modes to be present, but in the form of point band-touching nodes rather than a Fermi surface.

To connect Eq. (15) with the standard chiral anomaly we now note the following. If we focus only on the low-energy modes, Weyl semimetal appears to have a larger symmetry group than it actually has. Its true microscopic symmetry group is $U(1) \times \mathbb{Z}$,

where $U(1)$ corresponds to the electric charge conservation and $\mathbb{Z}$ to lattice translations (other discrete crystal symmetries, such as rotations, are irrelevant here). At low energies, however, the symmetry group appears to be $U(1)_L \times U(1)_R$, which corresponds to separate conservation of Weyl fermions of left (L) and right (R)-handed chirality. This symmetry group, if it were a true microscopic symmetry, would be anomalous, in the sense that it could not be realized in any 3D lattice model, but could only appear on the surface of a four-dimensional (4D) topological insulator, described by the following topological field theory

$$S = \frac{i}{6} \frac{e}{\Phi_0^2} \int (A_R \wedge dA_R \wedge dA_R - A_L \wedge dA_L \wedge dA_L), \quad (16)$$

where $A_{R/L}$ are $U(1)$ gauge fields, corresponding to the separate $U(1)_{R/L}$ symmetries. We now write $A_R = A + \tilde{Q}\tilde{A}$ and $A_L = A - \tilde{Q}\tilde{A}$, where $\tilde{A}$ is a chiral $U(1)$ gauge field, which couples antisymmetrically to fermions of opposite chirality and $\tilde{Q}$ is the corresponding "charge." This gives

$$S = i\tilde{Q} \frac{e}{\Phi_0^2} \int \tilde{A} \wedge dA \wedge dA. \quad (17)$$

On the 3D boundary of this 4D topological insulator, Eq. (17) becomes

$$S = i\tilde{Q} \frac{e}{\Phi_0^2} \int \tilde{A} \wedge A \wedge dA. \quad (18)$$

If we now identify $\tilde{Q} = Qd = \pi\lambda$, i.e. the dimensionless magnitude of the momentum of the two Weyl points (i.e. translational symmetry charge) and $\tilde{A} = e^2\Phi_0/2\pi$, we get precisely Eq. (15), which describes topological response of the physical 3D Weyl semimetal. The reason Eq. (15) can exist in a stand-alone 3D system, rather than a boundary of a 4D topological insulator, is that the physical translational symmetry group is $\mathbb{Z}$ rather than $U(1)$ and, moreover, translation is not a truly "internal" symmetry, like chiral charge conservation. Nevertheless, formally Eq. (15) and (18) are identical, which does lead to a number of unique observable phenomena in topological semimetals, which are usually described as consequences of the chiral anomaly. These are discussed in the following section.

Topological magnetotransport phenomena in semimetals

This section describes some of the observable phenomena, which are encoded in Eq. (15). If we vary the action with respect to A_x , A_y and e_z^z , this gives the Hall conductance per atomic plane

$$G_{xy} = \lambda \frac{e^2}{h}, \quad (19)$$

which in a perfect crystal is equivalent to the Hall conductivity, given by Eq. (10). Expressing this in terms of conductance per atomic plane eliminates the dependence on a nonuniversal lattice constant d , leaving only the pure number λ . A noninteger value of the Hall conductance per atomic plane in units of e^2/h is impossible in a gapped insulator (unless it has topological order), which is another way to see that gapless modes must be present in a Weyl semimetal.

The noninteger Hall conductance of Eq. (19) is a property that is specific to magnetic Weyl semimetals with broken TR symmetry. A more universal property, common, in some form, to all point-node topological semimetals, is revealed by looking at Eq. (15) from a different angle. Suppose a straight magnetic flux tube along the z -direction, carrying a quantum of flux Φ_0 , is inserted into the sample. Eq. (15) tell us that the action, describing this one-dimensional (1D) magnetic flux tube, is given by

$$S = ie\lambda \int e^z \wedge \mathbf{A}. \quad (20)$$

This action describes a 1D metal, which has a noninteger charge per unit cell of

$$\rho d = i \frac{\delta S}{\delta A_0 \delta e_z^z} = e\lambda, \quad (21)$$

where ρ is the charge density. The Fermi momentum of this metal is

$$k_F = \pi\rho = \frac{\pi\lambda}{d} = Q, \quad (22)$$

which means that the 1D band dispersion crosses zero energy at the locations of the band-touching nodes of the 3D Weyl semimetal.

This is a simple demonstration of a fundamental property, shared (with some modifications) by all 3D point-node topological semimetals, namely the existence of a special Landau level, or more generally levels, which cross the Fermi energy at the locations of the band-touching nodes, see Fig. 4. In a magnetic Weyl semimetal, discussed above, a magnetic field B , applied along the z -direction, generates

Fig. 4 Landau levels of a Weyl semimetal with a pair of Weyl nodes at $k_z = \pm Q$.

$$N_\Phi = \frac{BL^2}{\Phi_0}, \quad (23)$$

1D channels, i.e. one per every flux quantum, which corresponds to a magnetic-field-dependent charge density of

$$\rho = \frac{e\lambda}{d} \frac{B}{\Phi_0}. \quad (24)$$

According to the Streda formula, this corresponds to the Hall conductivity

$$\sigma_{xy} = \frac{\partial \rho}{\partial B} = \frac{e^2}{h} \frac{\lambda}{d}, \quad (25)$$

which agrees with Eq. (10).

Aside from the Hall conductivity of magnetic Weyl semimetals, this Landau level is responsible for all the special magnetotransport phenomena in 3D point-node topological semimetals. Consider diffusive transport equations for a Weyl semimetal with a single pair of opposite-chirality nodes, for simplicity. There are two conserved quantities: total electron density $n = n_R + n_L$ and chiral electron density $n_c = n_R - n_L$, where $n_{R/L}$ are the densities of right (R) and left (L)-handed electrons. The transport equations for n and n_c are given by

$$\begin{aligned} \frac{\partial n}{\partial t} &= D \nabla^2 (n + gV) + \mathbf{\Gamma} \cdot \nabla n_c, \\ \frac{\partial n_c}{\partial t} &= D \nabla^2 n_c - \frac{n_c}{\tau_c} + \mathbf{\Gamma} \cdot \nabla (n + gV). \end{aligned} \quad (26)$$

Here V is the external electrostatic potential, $D \sim v_F^2 \tau$ is the diffusion constant, τ is the momentum relaxation time, which depends on the density of states g and the strength of the impurity scattering. $\tau_c \gg \tau$ is the chirality relaxation time, which is assumed to be much longer than the momentum relaxation time. The density of states g is taken to be finite even in the absence of the external magnetic field $\mathbf{B}$. This may be due to the Fermi energy not exactly coinciding with the location of the Weyl nodes, which will generically be the case in the presence of impurities. In this case $g = \varepsilon_F^2 / (\pi^2 \hbar^3 v_F^3) = k_F^2 / (\pi^2 \hbar v_F)$ for a pair of Weyl nodes. A finite density of states may also be directly induced by strong enough disorder even when $\varepsilon_F = 0$.

$\mathbf{\Gamma}$ is a new transport coefficient, related to the chiral anomaly, given by

$$\mathbf{\Gamma} = \frac{\hat{B}}{2\pi^2 \hbar^2 g} \sim \frac{v_F}{(k_F \ell_B)^2} \hat{B}, \quad (27)$$

where $\ell_B = \sqrt{\hbar/eB}$ is the magnetic length and $\hat{B}$ is a unit vector in the direction of the magnetic field. Since the total electron number is exactly conserved, we may read off the expression for the electric current from the first of Eq. (26)

$$\mathbf{j} = \frac{\sigma}{e} \nabla \mu + e g \mu_c \mathbf{\Gamma}, \quad (28)$$

where $\sigma = e^2 g D$ is the diagonal conductivity and μ, μ_c are the electrochemical potentials, associated with the total and chiral particle densities. The first term in Eq. (28) is the standard Ohm's law. The second term describes an extra contribution to the electrical conductivity, which arises from the chiral anomaly, namely the N_Φ 1D conduction channels, which are opened up by the applied field. It is clear that this additional contribution to the current can have a dramatic effect in transport, since it is associated with first derivative terms in the transport equations Eq. (26), while the standard drift-diffusion terms which involve second derivatives.

To quantify this effect, it is useful to find the eigen-modes of the transport equations, which are given by

$$\omega_{\pm} = \pm\omega_0 - i(Dq^2 + 1/2\tau_c), \quad (29)$$

where

$$\omega_0 = \sqrt{(\Gamma q)^2 - 1/4\tau_c^2}. \quad (30)$$

We now note that the frequency ω_0 is purely imaginary at the smallest momenta when

$$q < \frac{1}{2\Gamma\tau_c} = \frac{L_a}{2L_c^2} \equiv \frac{1}{L_*}, \quad (31)$$

where we have introduced two length scales

$$L_c = \sqrt{D\tau_c}, \quad (32)$$

which has the meaning of the chiral charge diffusion length, and

$$L_a = \frac{D}{\Gamma} \sim \ell(k_F\ell_B)^2, \quad (33)$$

where $\ell = v_F\tau$ is the mean free path. L_a is a magnetic-field-related length scale, distinct from the magnetic length, which arises from the chiral anomaly. It is a long hydrodynamic length scale in the weak magnetic field regime, in the sense that $L_a \gg \ell$, but it may still be much smaller than either the chiral charge diffusion length L_c or the sample size L . In fact, the ratio L_c/L_a quantifies the strength of the chiral-anomaly-related transport phenomena, as will be seen below.

Thus when $q < 1/L_*$ the eigenfrequencies of the transport equations are purely imaginary, which corresponds to ordinary diffusion (nonpropagating) modes. However, when $q > 1/L_*$ (which may be a very small momentum when the ratio L_c/L_a is large), ω_0 is real, which signals the emergence of a pair of propagating modes in this regime. The modes are only weakly damped as long as

$$\omega_0 \approx \Gamma q > Dq^2, \quad (34)$$

which defines the upper limit on the wavevector $q = 1/L_a$, above which the propagating modes disappear. The propagating modes thus exist in the interval

$$1/L_* < q < 1/L_a. \quad (35)$$

This interval is significant when $L_c/L_a \gg 1$. On the other hand, when $L_a > L_c$, propagating modes do not exist for any q and one obtains a pair of standard diffusion modes

$$\omega_+ = -iDq^2, \omega_- = -iDq^2 - i/\tau_c, \quad (36)$$

which corresponds to independent diffusion of the total and the chiral charge densities.

The propagating mode of Eq. (34) signals the emergence of quasiballistic transport at long enough length scales. This may be seen explicitly by solving Eq. (26) in the steady state, assuming a uniform sample of linear size L , attached to metallic leads in the z -direction (i.e. the current flows along the magnetic field). One obtains the following expression for the scale-dependent sample conductance

$$G(L) = \frac{e^2 N_\phi}{h} F(L/L_a, L/L_c), \quad (37)$$

where the scaling function $F(x, \gamma)$ is given by

$$F(x, \gamma) = \frac{(1 + \gamma^2/x^2)^{3/2}}{\frac{\gamma^2}{2x} \sqrt{1 + \gamma^2/x^2} + \tanh\left(\frac{x}{2} \sqrt{1 + \gamma^2/x^2}\right)}. \quad (38)$$

This scaling function exhibits crossover behaviors which exactly match the corresponding crossovers in the wavevector dependence of the diffusion modes, found above.

Indeed, when $x \ll \gamma$, which means $L_a \gg L_c$, we have $F(x, \gamma) \approx 2/x$, which gives

$$G(L) \approx e^2 gDL = \sigma L, \quad (39)$$

which is simply the standard Ohmic conductance, with a small magnetic-field dependent correction, which goes as $(L_c/L_a)^2$, and which we have ignored here for the sake of brevity. This arises in the regime, in which we have two independent diffusion modes, given by Eq. (36), corresponding to independent diffusion of the total and the chiral charges.

On the other hand, when $L_a \ll L_c$ or $x \gg \gamma$, we obtain

$$F(x, \gamma) \approx \frac{1}{\gamma^2/2x + \tanh(x/2)}. \quad (40)$$

This exhibits a regime of quasiballistic conductance with

$$G(L) \approx \frac{e^2 N_\phi}{h}, \quad (41)$$

which is realized when

$$L_a < L < L_*. \quad (42)$$

This corresponds precisely to the range of the wavevectors q in Eq. (35), for which propagating modes exist when $L_a \ll L_c$. Thus, one of the observable manifestations of the existence of quasi-1D propagating modes in a topological semimetal is the quasiballistic conductance, given by Eq. (41). Upon further increase of the sample size, a crossover back into the diffusive regime happens when $\gamma^2 > x$, or equivalently when the sample size exceeds the length L_*

$$L > L_* \gg L_c. \quad (43)$$

In this regime the conductance is dominated by the field-dependent chiral anomaly contribution, but with $\propto B^2$, instead of $\propto B$, dependence

$$G(L) = \sigma(L_c/L_a)^2 L. \quad (44)$$

When $L_a > L_c$ this result still holds in the infinite sample limit, but with Eq. (44) only representing a subdominant correction to the Ohmic conductance.

Perhaps the clearest evidence for the chiral anomaly can come from the measurement of the optical magneto-conductivity. This may be evaluated using the full frequency and wavevector-dependent density response function $\chi(q, \omega)$, with ladder impurity vertex corrections

$$\sigma_{zz}(\omega) = -e^2 \lim_{q \rightarrow 0} \frac{i\omega}{q^2} \chi(q, \omega). \quad (45)$$

A straightforward calculation then gives

$$\sigma_{zz}(\omega) = \frac{\sigma}{1 - i\omega\tau} \frac{1 - i\omega\tau_c + (L_c/L_a)^2}{1 - i\omega\tau_c}. \quad (46)$$

Evaluating the real part, one obtains

$$\text{Re } \sigma_{zz}(\omega) = \frac{\sigma}{1 + \omega^2\tau^2} \left[1 + \left(\frac{L_c}{L_a} \right)^2 \frac{1 - \omega^2\tau\tau_c}{1 + \omega^2\tau_c^2} \right]. \quad (47)$$

The prefactor in Eq. (47) is the standard Drude expression for the optical conductivity of a metal. The part in the square brackets is a correction that arises in a topological semimetal as a consequence of the chiral anomaly. This correction represents transfer of the spectral weight from high frequencies into a new low-frequency peak, whose width scales with the chiral charge relaxation rate $1/\tau_c$, while height is proportional to the ratio $(L_c/L_a)^2$. Importantly, Eq. (47) satisfies the exact f -sum rule

$$\int_0^\infty d\omega \text{Re } \sigma_{zz}(\omega) = \frac{\pi\sigma}{2\tau}, \quad (48)$$

which means that the appearance of the new low-frequency peak indeed represents spectral weight transfer, as it should, see Fig. 5. The extra zero-frequency peak in the optical conductivity is a direct evidence of the opening up of a new transport channel (the zeroth Landau level) by the applied magnetic field.

Fig. 5 Frequency-dependent conductivity for $L_c/L_a = 1$ (solid line) and $L_c/L_a = 0$ (dashed line), and $\tau/\tau_c = 0.04$.

Conclusion

In conclusion, we have described topological properties of Dirac and Weyl semimetals. These may be viewed as a consequence of the chiral anomaly and manifest in observable phenomena: intrinsic anomalous Hall effect with a non-integer Hall conductance per atomic plane; negative longitudinal magnetoresistance and scale-dependent quasiballistic transport; extra magnetic-field-dependent low-frequency peak in the optical conductivity, whose width is determined by the chirality relaxation rate.

Abstract

Topological insulators are characterized by insulating bulk and conducting surface, the latter is a necessity consequence of the nontrivial topology of the wavefunctions forming the valence band. This chapter gives a historical overview of the discovery of topological insulators and a concise description of the Z_2 topology which defines them. The concept of topological insulators have been extended to various other topologies, giving rise to the recognition of further topological states of matter such as topological crystalline insulators and higher-order topological insulators. Representative materials of topological insulators, their synthesis techniques, and the ways for the experimental confirmation of the topological nature are introduced. Among the interesting phenomena derived from topological insulators, topological superconductivity, Majorana zero modes, and quantum anomalous Hall effect are briefly discussed.

Key points

- Bulk-boundary correspondence guarantees the appearance of gapless boundary states in a topological material.
- Topological insulators are defined by the Z_2 topology that was theoretically discovered in 2005.
- Spin-momentum locking is a key characteristic of the boundary states of topological insulators, allowing for topological superconductivity to show up in proximity to a conventional superconductor.
- Most topological-insulator materials are not really insulating in the bulk, but bulk-insulating samples can be obtained for $\text{Bi}_2\text{Te}_2\text{Se}$, $\text{Bi}_{2-x}\text{Sb}_x\text{Te}_3$, $\text{Bi}_{2-x}\text{Sb}_x\text{Te}_{3-y}\text{Se}_y$, HgTe , and WTe_2 .
- Quantum anomalous Hall effect can be realized in ferromagnetic topological insulators.

Introduction

Topological insulators (TIs) are a class of insulators whose occupied states are characterized by a nontrivial topological invariant. In the widest sense of the term, a two-dimensional (2D) electron gas in high magnetic fields showing the quantum Hall effect can be considered a TI, because such a system is characterized by a non-zero Chern number, which is a prototypical topological invariant for a time-reversal-breaking system. However, the term TI is most commonly used for time-reversal-invariant insulators that are characterized by a non-zero Z_2 index. Both 2D and three-dimensional (3D) systems can be TIs, and a 2D TI may also be called a quantum spin Hall insulator for historical reasons. While a 2D TI is characterized by a single Z_2 index, a combination of four Z_2 indices is necessary to fully characterize 3D TIs, which can be subdivided into strong TIs and weak TIs based on the Z_2 indices. New types of TIs characterized by different topological invariants, such as topological crystalline insulators or higher-order TIs, have been discovered with concrete materials realizations.

An important consequence of the nontrivial topology of TIs is that a gapless boundary state necessarily shows up when the material is physically terminated. This is because the nontrivial topology is a discrete characteristic of the gapped energy states,

Fig. 1 Schematic picture of the spin-momentum locking in the topological surface states of a 3D TI. Electrons moving in opposite directions (depicted by green or blue lines with arrows) have opposite spin directions (red arrows); note that spins are perpendicular to the momentum.

which cannot change as long as the energy gap remains open. Since the vacuum (i.e. outside of the TI) is also gapped and is topologically trivial, there is a collision of different topologies at the boundary. In order for the topology to change across the boundary, the gap must close there. Therefore, 3D TIs are always associated with gapless surface states, and so are two-dimensional 2D TIs with gapless edge states. Furthermore, the resulting gapless states always reflect the topological character of the bulk states, which is called bulk-boundary correspondence.

In 2D and 3D TIs, their nontrivial topology is protected by time-reversal symmetry (TRS). There are special points in the Brillouin zone called time-reversal-invariant momenta, at which the momentum $\mathbf{k}$ is invariant upon time reversal. The Kramers theorem dictates that the gapless boundary states of a TI must be degenerate at a time-reversal-invariant momentum; as a result, the energy dispersion of the boundary states of a TI takes the form of a massless Dirac cone located at one of the time-reversal-invariant momenta. This massless Dirac cone is spin-non-degenerate, and the requirement of TRS means that the direction of the spin must be opposite between the states with $\mathbf{k}$ and $-\mathbf{k}$. This relationship is called spin-momentum locking (see Fig. 1), which is one of the most important characteristics of TIs. In a 2D TI, the spin-momentum locking in the 1D edge state leads to the quantum spin Hall effect. When the TRS is broken, the gapless (or massless) nature of the Dirac cone is no longer protected by the topology and a gap may open at the Dirac point, but it does not mean that the Dirac cone disappears altogether upon TRS breaking.

Historical perspective

The quantum Hall effect (QHE) was discovered in 1980 by von Klitzing et al. in a high-mobility 2D semiconductor under high magnetic fields (Klitzing et al., 1980). In 1982, Thouless, Kohmoto, Nightingale, and den Nijs (TKNN) (Thouless et al., 1982) calculated the Hall conductance σ_{xy} of a Landau-quantized 2D system and showed that, when the chemical potential lies in a gap between Landau levels, $\sigma_{xy} = \nu(e^2/h)$ with an integer ν . This integer ν , often called TKNN invariant, was later shown to be nothing but the first Chern number of a 2D TRS-breaking topological system (Kohmoto, 1985). Therefore, the importance of topology in condensed matter was already recognized in the QHE system in 1980s.

Another important event preceding TIs was the discovery in 2004 of the spin Hall effect (Kato et al., 2004), the appearance of transverse spin current in response to longitudinal electric field. The spin Hall effect in nonmagnetic systems is fundamentally related to the anomalous Hall effect in ferromagnets (Nagaosa et al., 2010) and it can have both intrinsic and extrinsic origins. The intrinsic mechanism stems from the Berry curvature of the valence-band Bloch wavefunctions integrated over the Brillouin zone. Since such an integral can be non-zero even in an insulator, Murakami, Nagaosa, and Zhang proposed the idea of spin Hall insulator (Murakami et al., 2004), which is a gapped insulator with a finite spin Hall conductivity. Although this idea was later shown to be unrealistic as a bulk property (Onoda and Nagaosa, 2005), this triggered the subsequent proposal of the quantum spin Hall insulator in 2005 by Kane and Mele (Kane and Mele, 2005a, 2005b), who considered the edge states associated with an insulating 2D bulk. The ingenious proposal by Kane and Mele provided a concrete model (graphene with spin-orbit coupling) to realize the bulk band gap and gapless edge states in zero magnetic field (Kane and Mele, 2005a). More importantly, Kane and Mele recognized that the electronic states of their quantum spin Hall insulator is characterized by a novel topology specified by a Z_2 index (Kane and Mele, 2005b). This theoretical discovery of the Z_2 topology in insulators was an important step in our understanding of topological phases of matter. Experimentally, since the spin-orbit coupling in graphene is very weak, it is unfortunately difficult to observe the quantum spin Hall effect predicted in the Kane-Mele model. However, in 2006 Bernevig, Hughes, and Zhang proposed another 2D model to produce a Z_2 topological phase based on the band structure of HgTe, and they predicted that a CdTe/HgTe/CdTe quantum well should be a quantum spin Hall insulator (Bernevig et al., 2006). This prediction was verified in 2007 by Konig et al. (2007), who observed the quantization of the longitudinal conductance to $2e^2/h$ in zero magnetic field, giving evidence for the gapless edge states in the insulating regime.

In parallel with the experimental verification of the Z_2 topology in 2D, the topological classification of time-reversal-invariant insulators was extended to 3D systems. It was shown in 2006–2007 that four Z_2 indices are needed to fully characterize the topology for 3D (Fu et al., 2007; Moore and Balents, 2007; Roy, 2009). The term “topological insulator” was coined by Moore and Balents when they proposed the existence of topological systems in 3D (Moore and Balents, 2007). Fu and Kane made a concrete prediction

that the $\text{Bi}_{1-x}\text{Sb}_x$ alloy in the insulating composition should be a 3D TI, and they further proposed that the nontrivial topology can be verified with the angle-resolved photoemission spectroscopy (ARPES) by counting the number of times the surface states cross the Fermi energy between two time-reversal-invariant momenta (Fu and Kane, 2007). The proposed experiment was conducted by Hsieh et al. who reported in 2008 that $\text{Bi}_{1-x}\text{Sb}_x$ is indeed a 3D TI (Hsieh et al., 2008).

Before the $\mathbb{Z}_2$ topology was theoretically discovered by Kane and Mele, a time-reversal-invariant topological state was conceived for four-dimensional (4D) systems, for which the topological invariant is an integer (Zhang and Hu, 2001). The effective field theory constructed for such 4D topological systems (Bernevig et al., 2002) was shown to be useful for 3D and 2D TIs (Qi et al., 2008), leading to interesting predictions regarding topological magnetoelectric effects (Qi et al., 2008).

Theory of topological insulators

The Berry connection of the Bloch wavefunctions in the momentum space plays the key role in the theory of topological insulators. Let us consider a band insulator described by a Bloch Hamiltonian $H(\mathbf{k})$ with the crystal momentum $\mathbf{k}$. The eigenstates are given by the solutions of the Bloch equation,

$$H(\mathbf{k})|u_n(\mathbf{k})\rangle = E_n(\mathbf{k})|u_n(\mathbf{k})\rangle. \quad (1)$$

The Berry connection $\mathcal{A}^{(n)}(\mathbf{k})$ is defined by

$$\mathcal{A}^{(n)}(\mathbf{k}) \equiv i\langle u_n(\mathbf{k})|\partial_{\mathbf{k}}u_n(\mathbf{k})\rangle, \quad (2)$$

which measures the rate of change in the wavefunction $|u_n(\mathbf{k})\rangle$ in the momentum space.

A gauge-invariant quantity constructed from $\mathcal{A}^{(n)}(\mathbf{k})$ is the Berry phase, which is defined by

$$\gamma_n[C] \equiv \oint_C d\mathbf{k} \cdot \mathcal{A}^{(n)}(\mathbf{k}), \quad (3)$$

where the line integral is performed along a closed path C in the momentum space and the gauge is chosen so that $\mathcal{A}^{(n)}(\mathbf{k})$ is non-singular on C . Note that $\gamma_n[C]$ has a freedom of $2\pi N$ with integer N and is not strictly gauge-invariant, but $e^{i\gamma_n[C]}$ is.

Another gauge-invariant quantity that can be constructed from $\mathcal{A}^{(n)}(\mathbf{k})$ is the field strength defined by

$$\mathcal{F}_{ij}^{(n)}(\mathbf{k}) \equiv \partial_{k_i}\mathcal{A}_{k_j}^{(n)}(\mathbf{k}) - \partial_{k_j}\mathcal{A}_{k_i}^{(n)}(\mathbf{k}). \quad (4)$$

For a 2D system, the Chern number of the n -th band is defined as the integral of the field strength $\mathcal{F}_{ij}^{(n)}(\mathbf{k})$ over the 2D Brillouin zone:

$$Ch^{(n)} = \frac{1}{2} \int_{\text{2D BZ}} dk_x dk_y \mathcal{F}_{xy}^{(n)}(\mathbf{k}). \quad (5)$$

This integral vanishes if $\mathcal{A}^{(n)}(\mathbf{k})$ has no singularity over the Brillouin zone. But if $\mathcal{A}^{(n)}(\mathbf{k})$ has a singularity at $\mathbf{k}_0$, the gauge transformation

$$\mathcal{A}^{(n)'}(\mathbf{k}) = \mathcal{A}^{(n)}(\mathbf{k}) - \partial_{\mathbf{k}}\phi_n(\mathbf{k}) \quad (6)$$

in the region R including $\mathbf{k}_0$ can make $\mathcal{A}^{(n)'}(\mathbf{k})$ to have no singularity in R . Using the Stokes' theorem, Eq. (5) becomes

$$Ch^{(n)} = \frac{1}{2} \int_{\partial R} d\mathbf{k} \cdot \partial_{\mathbf{k}}\phi_n(\mathbf{k}), \quad (7)$$

where ∂R is the boundary of R . Because $e^{i\phi_n(\mathbf{k})}$ is a unique function on ∂R , this $Ch^{(n)}$ must be an integer. For a 2D insulator, the total Chern number Ch of the occupied bands is given by

$$Ch = \sum_{E_n < E_F} Ch^{(n)}. \quad (8)$$

Note that Ch can be finite only when the time-reversal symmetry is broken, because $Ch = -Ch$ under time-reversal symmetry.

The key insight of Kane and Mele (2005b) was that the Kramers degeneracy makes it possible to define a new topological invariant (i.e. the $\mathbb{Z}_2$ index) for 2D time-reversal-invariant systems. The time reversal operator $\mathcal{T}$ obeys $\mathcal{T}^2 = -1$ for spin- $\frac{1}{2}$ electrons, and the anti-unitarity of $\mathcal{T}$ yields

$$\langle \mathcal{T}u | \mathcal{T}v \rangle = \langle v | u \rangle \quad (9)$$

for any states $|u\rangle$ and $|v\rangle$. This leads to the conclusion that a state $|u\rangle$ is orthogonal to its time-reversal partner $\mathcal{T}|u\rangle$, i.e. $\langle u | \mathcal{T}u \rangle = 0$, because $\langle u | \mathcal{T}u \rangle = \langle \mathcal{T}^2 u | \mathcal{T}u \rangle = -\langle u | \mathcal{T}u \rangle$. In a time-reversal-invariant system, $|u\rangle$ and $\mathcal{T}|u\rangle$ have the same energy, and hence their orthogonality means a guaranteed two-fold degeneracy, which is the essence of the Kramers degeneracy.

The time-reversal invariance makes the Bloch Hamiltonian $H(\mathbf{k})$ in Eq. (1) to have the following property:

$$\mathcal{T}H(\mathbf{k})\mathcal{T}^{-1} = H(-\mathbf{k}). \quad (10)$$

Hence, for an eigenstate $|u_n(\mathbf{k})\rangle$ of $H(\mathbf{k})$, its Kramers partner $\mathcal{T}|u_n(\mathbf{k})\rangle$ is an eigenstate of $H(-\mathbf{k})$. The orthogonality between $|u_n(\mathbf{k})\rangle$ and $\mathcal{T}|u_n(\mathbf{k})\rangle$ means that the latter can also be written by using a different eigenstate $|u_{n'}(\mathbf{k})\rangle$ of $H(\mathbf{k})$ as $|u_{n'}(-\mathbf{k})\rangle$. Hereafter, we write such a Kramers pair ($|u_n(\mathbf{k})\rangle, |\mathcal{T}u_n(\mathbf{k})\rangle$) as ($|u_n^I(\mathbf{k})\rangle, |u_n^{II}(\mathbf{k})\rangle$). Due to the phase ambiguity of the eigenstates, there is a general relation

$$|u_n^{II}(\mathbf{k})\rangle = e^{i\varphi_n(\mathbf{k})}\mathcal{T}|u_n^I(-\mathbf{k})\rangle, \quad (11)$$

with $\varphi_n(\mathbf{k})$ the gauge degree of freedom.

The Z_2 index was originally provided in the form of a Pfaffian (Kane and Mele, 2005b), but here we derive it as a variant of the spin Chern number (Sheng et al., 2006), which is well-defined when a 2D system has a fixed spin orientation, say S_z . In the diagonal basis of S_z , the Bloch Hamiltonian is written as

$$H(\mathbf{k}) = \begin{pmatrix} H_\uparrow(\mathbf{k}) & 0 \\ 0 & H_\downarrow(\mathbf{k}) \end{pmatrix}, \quad (12)$$

where $H_\uparrow(\mathbf{k})$ and $H_\downarrow(\mathbf{k})$ are for the $S_z = 1/2$ and $S_z = -1/2$ sector, respectively. With this separation of $H(\mathbf{k})$, the spin Chern number $Ch_\uparrow$ and $Ch_\downarrow$ are defined as the Chern number of $H_\uparrow(\mathbf{k})$ and $H_\downarrow(\mathbf{k})$, respectively. Since each spin sector breaks time-reversal symmetry, the spin Chern number can be nonzero even for a time-reversal-invariant system, although the total Chern number must always vanish (i.e. $Ch_\uparrow + Ch_\downarrow = 0$) due to time-reversal symmetry.

In general, spin-orbit coupling breaks spin conservation, and thus the spin Chern number is not well-defined in a spin-orbit coupled system. However, in the presence of time-reversal symmetry, one can derive an analogous topological number as follows: Instead of the spin eigen-sectors, we use Kramers pairs ($|u_n^I(\mathbf{k})\rangle, |u_n^{II}(\mathbf{k})\rangle$) to divide the Hilbert space into two subspaces, and then introduce the Chern numbers in those subspaces,

$$\begin{aligned} Ch_I &= \frac{1}{2\pi} \int_{\text{2D BZ}} dk_x dk_y \mathcal{F}_{xy}^{I(-)}(\mathbf{k}), \\ Ch_{II} &= \frac{1}{2\pi} \int_{\text{2D BZ}} dk_x dk_y \mathcal{F}_{xy}^{II(-)}(\mathbf{k}), \end{aligned} \quad (13)$$

where $\mathcal{F}_{xy}^{I(-)}(\mathbf{k})$ and $\mathcal{F}_{xy}^{II(-)}(\mathbf{k})$ are the field strengths of the Berry connections $\mathcal{A}^{I(-)}(\mathbf{k})$ and $\mathcal{A}^{II(-)}(\mathbf{k})$, which are defined for the occupied states as

$$\begin{aligned} \mathcal{A}^{I(-)}(\mathbf{k}) &= i \sum_{E_n < E_F} \langle u_n^I(\mathbf{k}) | \partial_{\mathbf{k}} u_n^I(\mathbf{k}) \rangle, \\ \mathcal{A}^{II(-)}(\mathbf{k}) &= i \sum_{E_n < E_F} \langle u_n^{II}(\mathbf{k}) | \partial_{\mathbf{k}} u_n^{II}(\mathbf{k}) \rangle. \end{aligned} \quad (14)$$

These Chern numbers share the same property as the spin Chern numbers: they take integer numbers, and $Ch_I + Ch_{II} = 0$ due to time-reversal symmetry. However, Ch_I and Ch_{II} themselves are not really well-defined, because the superscripts I and II do not have any physical meaning, and hence they can be exchanged; such an exchange leads to $Ch_I \rightarrow Ch_{II}$ ($= -Ch_I$) and $Ch_{II} \rightarrow Ch_I$ ($= -Ch_{II}$), and thus the Chern numbers Ch_I and Ch_{II} cannot be unique.

Nevertheless, by considering only the parity of these Chern numbers, i.e. $(-1)^{Ch_I}$ and $(-1)^{Ch_{II}}$, this ambiguity can be avoided; namely, because of the constraint $Ch_I = -Ch_{II}$, the parity satisfies $(-1)^{Ch_I} = (-1)^{-Ch_{II}} = (-1)^{Ch_{II}}$, making them robust against the exchange of the superscripts. As a result, we have a unique Z_2 index $(-1)^{v_{2D}}$ which is defined as

$$(-1)^{v_{2D}} \equiv (-1)^{Ch_I} = (-1)^{Ch_{II}}. \quad (15)$$

An insulator with $(-1)^{v_{2D}} = -1$ is topologically distinct from an ordinary insulator and such a system is called a 2D TI or a quantum spin Hall insulator. v_{2D} is called Z_2 topological invariant and takes the value 0 or 1.

The time-reversal invariance allows us to introduce Z_2 indices in three dimensions (Moore and Balents, 2007). A time-reversal-invariant momentum Γ_i is defined as a momentum-space point satisfying $-\Gamma_i = \Gamma_i + \mathbf{G}$ for a reciprocal lattice vector $\mathbf{G}$. In a 3D Brillouin zone, there are a total of eight such Γ_i 's and they can be indexed by using three integers n_a ($a = 1, 2, 3$) taking the value of 0 or 1 as

$$\Gamma_{i=(n_1, n_2, n_3)} = \frac{1}{2}(n_1 \mathbf{b}_1 + n_2 \mathbf{b}_2 + n_3 \mathbf{b}_3) \quad (16)$$

Fig. 2 The eight time-reversal-invariant momenta $\Gamma_i [i = (n_1, n_2, n_3)]$ in the 3D Brillouin zone having tetragonal symmetry. The time-reversal-invariant plane $\Sigma^a_{n_a}$ for $a = 2$ and $n_a = 1$ is hatched as an example.

with the primitive reciprocal lattice vectors $\mathbf{b}_i$ (see Fig. 2). Fixing one of the three n_a 's gives a group of four time-reversal-invariant momenta. For example, by fixing n_2 to be 1, one obtains four time-reversal-invariant momenta $\Gamma_{(n_1, 1, n_3)}$ with $n_1 = 0, 1$ and $n_3 = 0, 1$. These four time-reversal-invariant momenta specifies a distinct time-reversal-invariant plane $\Sigma^a_{n_a}$ in the 3D Brillouin zone (see Fig. 2 for the example of $\Sigma^a_{n_a}$ for $a = 2$ and $n_a = 1$). One can easily see that there are six distinct time-reversal-invariant planes in the 3D Brillouin zone.

It is easy to see that each time-reversal-invariant plane $\Sigma^a_{n_a}$ has its own Z_2 index $(-1)^{Ch(\Sigma^a_{n_a})}$. Hence, there are a total of six Z_2 indices that are defined in this manner, but they are not completely independent and the following constraints exist (Moore and Balents, 2007):

$$\begin{aligned} (-1)^{Ch(\Sigma^1_1) - Ch(\Sigma^1_0)} &= (-1)^{Ch(\Sigma^2_1) - Ch(\Sigma^2_0)} \\ &= (-1)^{Ch(\Sigma^3_1) - Ch(\Sigma^3_0)}. \end{aligned} \quad (17)$$

As a result, only the following four Z_2 indices are independent (Moore and Balents, 2007):

$$\begin{aligned} (-1)^{v_{2D}^a} &\equiv (-1)^{Ch(\Sigma^a_1)}, \quad (a = 1, 2, 3) \\ (-1)^{v_{3D}} &\equiv (-1)^{Ch(\Sigma^1_1) - Ch(\Sigma^1_0)} = (-1)^{Ch(\Sigma^1_1)} (-1)^{Ch(\Sigma^1_0)}. \end{aligned} \quad (18)$$

The first three Z_2 indices becomes nontrivial (i.e. -1) if the system is just a stack of 2D TIs, and these three are called weak indices. On the other hand, the last Z_2 index $(-1)^{v_{3D}}$ is intrinsic to 3D and this is called strong Z_2 index. An insulator with nontrivial strong Z_2 index is called a strong 3D TI, while those having only nontrivial weak indices are called weak 3D TIs. The set of four parameters $(v_{3D}, v_{2D}^1, v_{2D}^2, v_{2D}^3)$ constitutes the 3D Z_2 topological invariants to fully characterize the Z_2 topology of a 3D insulator.

When an insulator has inversion symmetry, the evaluation of the Z_2 indices becomes simple (Fu and Kane, 2007). The inversion operator P has the property $P^2 = 1$ and the Bloch Hamiltonian $H(\mathbf{k})$ of a centrosymmetric system satisfies

$$PH(\mathbf{k})P^{-1} = H(-\mathbf{k}). \quad (19)$$

From this relation, one can conclude that an eigenstate of $H(\mathbf{k})$ at $\mathbf{k} = \Gamma_i$ is simultaneously an eigenstate of P . Furthermore, because of the relation $[T, P] = 0$, a Kramers pair have a common eigenvalue $\xi_i = \pm 1$ of P :

$$\begin{aligned} P|u_n^I(\Gamma_i)\rangle &= \xi_i|u_n^I(\Gamma_i)\rangle, \\ P|u_n^{II}(\Gamma_i)\rangle &= \xi_i|u_n^{II}(\Gamma_i)\rangle. \end{aligned} \quad (20)$$

The Z_2 index in 2D is evaluated by using these ξ_i as

$$(-1)^{v_{2D}} = \prod_i \xi_i, \quad (21)$$

where the product is taken for all inequivalent Γ_i 's in 2D (there are 4 of them). The Z_2 indices for 3D systems are given by

$$(-1)^{v_{2D}^a} = \prod_{n_a=1; n_b \neq a} \xi_{i=(n_1 n_2 n_3)} \quad (22)$$

and

$$(-1)^{v_{3D}} = \prod_i \xi_i, \quad (23)$$

where the product for the strong index is taken for all eight Γ_i 's in the 3D Brillouin zone.

Model Hamiltonian of A 3D topological insulator

The nontrivial electronic structure of TIs stems from strong spin-orbit coupling. As an example, here we consider a prototypical topological insulator, Bi_2Se_3 . Its bulk bands near the Fermi energy are mainly derived from the p_z orbitals of two inequivalent Se atoms in the unit cell, which makes the effective Hamiltonian to have a 4×4 matrix form (Zhang et al., 2009)

$$H_{\text{TI}}(\mathbf{k}) = (m_0 - m_1 k^2) \sigma_x + v_z k_z \sigma_y + v \sigma_z (k_x s_y - k_y s_x), \quad (24)$$

with σ_i denoting the Pauli matrices in the orbital space and s_i the Pauli matrices in the spin space. Note that the eigenstates of σ_z (i.e. $\sigma_z = \pm 1$) correspond to the two p_z orbitals. The third term is a result of strong spin-orbit coupling. Since the inversion operation exchanges the p_z orbitals, one can see that the inversion operator P is given by σ_x . The $H_{\text{TI}}(\mathbf{k})$ is invariant under the inversion P , i.e.

$$PH_{\text{TI}}(-\mathbf{k})P^{-1} = H_{\text{TI}}(\mathbf{k}). \quad (25)$$

The model Hamiltonian Eq. (24) focuses on the physics near the Γ point (i.e. $\mathbf{k} = 0$), and the strong Z_2 index given by Eq. (23) can be evaluated by taking the multiple of the parity of the occupied states at $\mathbf{k} = 0$ and at the Brillouin zone boundary ($k \rightarrow \infty$ in this model).

Let us now consider the case $m_0 > 0$ and $m_1 > 0$ and examine if the system is topological. At $\mathbf{k} = 0$ we have $H_{\text{TI}}(\mathbf{k} = 0) = m_0 \sigma_x$, and hence the eigenstate with odd parity ($\sigma_x = -1$) becomes the occupied state when $m_0 > 0$. On the other hand, since we have $H_{\text{TI}}(\mathbf{k} \rightarrow \infty) \sim -m_1 k^2 \sigma_x$ at large k , the even-parity eigenstate becomes occupied when $m_1 > 0$. Thus, in this case, the strong Z_2 index (i.e. the multiple of the parity of the occupied states at $\mathbf{k} = 0$ and at $k \rightarrow \infty$) is -1 , meaning that the system is topological. More generally, one can infer that the system becomes topological when m_0 and m_1 have the same sign, which is expressed as

$$(-1)^{v_{3D}} = -\text{sgn}(m_0 m_1). \quad (26)$$

Physically, the condition for the system to become topological is that the parity of the occupied state switches at somewhere in the Brillouin zone between $\mathbf{k} = 0$ and $k \rightarrow \infty$; such a switching is called band inversion, and the above discussion shows that it is the band inversion which makes Bi_2Se_3 to be topological.

Let us now derive the topological surface states from $H_{\text{TI}}(\mathbf{k})$. We consider a surface at $z = 0$ with the insulator occupying the positive z region. The wavefunction at the surface has the form

$$\psi_{k_x, k_y}(z) = (e^{-\kappa_- z} - e^{-\kappa_+ z}) \begin{pmatrix} 0 \\ 1 \end{pmatrix}_\sigma \otimes u_s(k_x, k_y), \quad (27)$$

with

$$\kappa_\pm = -\frac{v_z}{2m_1} \pm \sqrt{\left(\frac{v_z}{2m_1}\right)^2 + k_x^2 + k_y^2 - \frac{m_0}{m_1}}. \quad (28)$$

Substituting $\psi_{k_x, k_y}(z)$ into the Schrödinger equation

$$H_{\text{TI}}(k_x, k_y, -i\partial_z) \psi_{k_x, k_y}(z) = E \psi_{k_x, k_y}(z), \quad (29)$$

one obtains a 2D Dirac equation

$$-v(k_x s_y - k_y s_x) u_s(k_x, k_y) = E u_s(k_x, k_y). \quad (30)$$

The term $k_x s_y - k_y s_x$ dictates the spin-momentum locking of the 2D Dirac fermions; namely, the spin is perpendicular to the surface momentum $\mathbf{k}_{2D}$ and lies within the surface plane.

Representative topological insulator materials

Usually, the TI materials become topological due to a band inversion, as one sees in the example in the previous section. The ultra-thin layer of HgTe is the most studied 2D TI. In the bulk HgTe, an inversion between p - and s -orbital bands gives the system a potential to be a TI, but these two bands are degenerate at the Γ point. The quantum-confinement effect in a thin layer opens a gap and makes the system to be a 2D TI (Bernevig et al., 2006). Applying an epitaxial strain to a thick layer of HgTe can also open a gap and make the system to be a 3D TI (Brune et al., 2011). Both TI phases have been experimentally confirmed. The highest mobility for the topological surface states of a 3D TI ($\sim 3 \times 10^4 \text{ cm}^2/\text{Vs}$) has been obtained in strained HgTe, although the bulk band gap attainable in strained HgTe would be limited to $\sim 22 \text{ meV}$ (Brune et al., 2011). The HgTe system has not gained a wide popularity in the TI research, because the growth of HgTe films requires elaborate facilities.

The quantum well of AlSb/InAs/GaSb/AlSb realizing an inverted band alignment was theoretically predicted (Liu et al., 2008) and experimentally confirmed (Knez et al., 2011) to be a 2D TI. The valence-band top of GaSb lies above the conduction-band bottom of InAs, so when thin layers of InAs and GaSb are in direct contact and they are both quantum confined, the resulting hole subband in GaSb may lie above the electron subband in InAs, realizing the band inversion necessary for a TI. However, it has been reported that the 2D TI phase in this system is very fragile against disorder and it is difficult to utilize the edge transport in this system (Shojaei et al., 2018).

The monolayer of WTe_2 has recently emerged as a promising 2D TI (Qian et al., 2014). WTe_2 is a van-der-Waals material and a monolayer flake can be obtained by exfoliation. It was shown that the quantized conductance due to the 1D edge states persists up to $\sim 100 \text{ K}$ in WTe_2 (Wu et al., 2018).

The first material that was confirmed (Hsieh et al., 2008) to be a 3D TI, $\text{Bi}_{1-x}\text{Sb}_x$, has a relatively high 2D carrier mobility of $\sim 10^4 \text{ cm}^2/\text{Vs}$ (Taskin and Ando, 2009). Also, it is relatively easy for this system to reduce the bulk carrier density to the 10^{16} cm^{-3} level in high-quality single crystals, making it possible, for example, to perform Landau level spectroscopy of the surface states via magneto-optics (Schafgans et al., 2012). The bulk band gap is up to $\sim 30 \text{ meV}$, which is large enough to detect the 2D transport properties at 4 K .

The most widely used 3D TIs for various studies of the topological phenomena are the family of materials having the tetradymite structure, Bi_2Se_3 , Bi_2Te_3 , Sb_2Te_3 , and their relatives. Their 3D TI nature was predicted in 2009 (Zhang et al., 2009), followed by

experimental confirmations of the existence of the topological surface states (Chen et al., 2009; Xia et al., 2009). Their crystal structure consists of covalently bonded quintuple layers (QLs), e.g. Se—Bi—Se—Bi—Se, that are stacked and weakly bonded by the van der Waals force, making it easy to cleave between QLs. High-quality single crystals and thin films of the binary compounds (Bi_2Se_3 , Bi_2Te_3 , Sb_2Te_3) can be relatively easily grown, which is one of the reasons for the popularity of these 3D TIs. It should be noted that those binary compounds are always conducting in the bulk and they are not really insulators, because bulk carrier doping due to naturally-occurring defects is unavoidable for entropy reasons. In 2010, the ternary compound $\text{Bi}_2\text{Te}_2\text{Se}$ was discovered to be the first bulk-insulating 3D TI material (Ren et al., 2010), where the concealment of Se in the middle of the QL plays a key role in achieving bulk insulation. It is also possible to synthesize bulk-insulating samples by employing the concept of compensation, namely, balancing donors and acceptors so that they cancel each other. A series of compositions to realize bulk-insulation have been identified for $\text{Bi}_{2-x}\text{Sb}_x\text{Te}_{3-y}\text{Se}_y$, which can be grown as high-quality bulk single crystals (Ren et al., 2011); for example, $\text{Bi}_{1.5}\text{Sb}_{0.5}\text{Te}_{1.7}\text{Se}_{1.3}$ shows a particularly low bulk conductivity (Taskin et al., 2011). Also, it has been shown that bulk-insulating thin films can be obtained by optimizing the growth condition of $\text{Bi}_{2-x}\text{Sb}_x\text{Te}_3$ (Zhang et al., 2011).

A less studied materials family of 3D TIs is TlBiSe_2 and its variants (TlBiTe_2 , TlSbTe_2 , $\text{TlBiSe}_{2-x}\text{S}_x$, etc.). In the solid solution $\text{TlBiSe}_{2-x}\text{S}_x$, one can access the topological phase transition between the TI and non-TI phases by tuning the x value (Sato et al., 2011; Xu et al., 2011). Bulk-insulating single crystals can be grown by tuning the composition in $\text{TlBi}_x\text{Sb}_{1-x}\text{Te}_2$ (Breunig et al., 2017), in which the compensation similar to that in $\text{Bi}_{2-x}\text{Sb}_x\text{Te}_3$ can be achieved.

An interesting material in the context of 3D TIs is SbB_6 , which may be a topological Kondo insulator in which the band gap originates from strong electron correlations (Dzero et al., 2010). There is strong evidence for surface-dominated transport at low temperature, but its topological nature remains controversial. Note that the surface-dominated transport can be observed in trivial insulators due to the formation of an accumulation or inversion layer, as reported for pure Te (von Klitzing and Landwehr, 1971).

Topological crystalline insulators

The Z_2 topology protected by time-reversal symmetry is not the only possible topological classification of band insulators. Another topology protected by point-group symmetries of the crystal lattice can also classify insulators, and a material that is nontrivial with such a topology is called a topological crystalline insulator (TCI) (Fu, 2011). Concrete topological invariants have been constructed for systems possessing four-fold (C_4) or six-fold (C_6) rotation symmetry (Fu, 2011) and also for systems having mirror symmetry (Hsieh et al., 2012).

In this context, SnTe is a TCI protected by mirror symmetry, even though it is trivial in the Z_2 topology. Here, the topology is specified by the topological invariant called mirror Chern number n_M , which evaluates the Chern number in only one of the two Hilbert subspaces divided according to the mirror eigenvalues (Teo et al., 2008). SnTe is characterized by $n_M = -2$, and its surface states on the $\{001\}$ surface present a peculiar double-Dirac-cone structure near the $\bar{X}$ points, which was theoretically predicted (Hsieh et al., 2012) and experimentally confirmed (Tanaka et al., 2012). Interestingly, the surface states on the $\{111\}$ surface have a different structure consisting of two different Dirac cones at $\bar{\Gamma}$ and $\bar{M}$ points (Tanaka et al., 2013b). The TCI phase has also been reported for $\text{Pb}_{0.77}\text{Sn}_{0.23}\text{Se}$, in which a transition to a topologically-trivial phase was observed upon increasing temperature (Dziawa et al., 2012). The topological phase transition also occurs as a function of the composition in $\text{Pb}_{1-x}\text{Sn}_x\text{Te}$, in which the TCI phase is realized for $x \in [0.25, 0.5]$ (Tanaka et al., 2013a; Xu et al., 2012).

The mirror Chern number n_M can also be used for time-reversal-invariant 3D TIs to further classify them (Teo et al., 2008). For example, $\text{Bi}_{1-x}\text{Sb}_x$ is a TI with Z_2 invariant $(1;111)$, and it can have $n_M = \pm 1$. The sign of n_M is called mirror chirality, which is related to the sign of the g factor. It was experimentally elucidated that $\text{Bi}_{1-x}\text{Sb}_x$ has the mirror chirality -1 (Nishide et al., 2010).

Higher-order topological insulators

It has been shown that 3D insulators can have a topology that leaves the surface to be gapped but some of their hinges or corners to accommodate symmetry-protected gapless states. The topological corner states may have fractional charge (Benalcazar et al., 2017). Such topological materials are called higher-order topological insulators — a 2nd-order 3D TI has gapless hinge states, and a 3rd-order 3D TI or a 2nd-order 2D TI has gapless corner states (Benalcazar et al., 2017; Schindler et al., 2018a, b). For example, in the presence of time-reversal and mirror symmetries, a 2nd-order 3D TI with helical hinge modes can be conceived, and SnTe has been proposed to be such a higher-order TI (Schindler et al., 2018a). Recently, Bi was elucidated to be a 2nd-order 3D TI in which the topology is protected by three-fold rotation and inversion symmetries, with the experimental proof of the existence of helical hinge states on the $\{111\}$ surface (Schindler et al., 2018b).

Experimental confirmation of TIs

In the case of 2D TIs, the existence of helical 1D edge states should be probed, which is possible only through quantum transport experiments using device structures. The existence of edge states can be confirmed through conductance quantization when the Fermi level is gate-tuned into the bulk band gap (Konig et al., 2007). Also, the helical spin polarization of the edge states may be detected by transport experiments using spin Hall effect (Bruene et al., 2012).

For 3D TIs, observation of the Dirac-cone surface states by ARPES experiments is the most straightforward. To firm up the identification of a TI, spin-resolved ARPES should be employed to detect the helical spin polarization of the Dirac cone (Hsieh et al., 2009; Nishide et al., 2010). In transport experiments, it is necessary to prepare a sufficiently bulk-insulating sample to observe Shubnikov-de Haas (SdH) oscillations coming from high-mobility surface carriers, but if it is successful, the 2D Dirac nature of the topological surface states can be elucidated by the dependence of the SdH-oscillation frequency on the direction of the applied magnetic fields as well as by the π Berry phase that can be identified via the Landau-level fan-diagram analysis (Taskin and Ando, 2011). The 2D Dirac nature may also be confirmed by scanning tunneling spectroscopy (STS) experiments in magnetic fields, through the observation of the peculiar Landau quantization in which the level spacing changes as $\sqrt{N}$ and the zero-energy Landau level is pinned to the Dirac point (Cheng et al., 2010).

Syntheses of TI materials

The synthesis of bulk single crystals of the chalcogenide 3D TI materials (Bi_2Se_3 , $\text{Bi}_2\text{Te}_2\text{Se}$, SnTe , etc.) are done in sealed evacuated quartz-glass tubes, because chalcogen atoms are volatile. The necessity of containment limits the range of applicable growth techniques, and the Bridgman method or vapor transport method are usually employed. In the Bridgman method, stoichiometric amounts of raw materials are first melted and then gradually cooled down in the presence of a temperature gradient, so that the crystallization starts at the cold end of the tube and the crystal grows as the solidification proceeds from this end. In the vapor transport technique, a chunk of polycrystalline material is put on the hot end of a sealed quartz-glass tube and the tube is kept for a long time in a furnace with a certain temperature gradient, during which the polycrystalline material sublimates and crystallizes at somewhere in the colder part.

For the growth of high-quality epitaxial thin films of TI materials, molecular beam epitaxy (MBE) technique is usually employed, in which the constituent elements are co-evaporated with suitable flux ratios. Although the lattice matching between the substrate and the grown material is usually very important for an epitaxial growth, in the case of the TI materials having the tetradymite structure, the lattice matching with the substrate is not crucial and the epitaxial growth proceeds in the so-called van-der-Waals epitaxy mode. For example, epitaxial growths of Bi_2Se_3 is possible on various substrates including $\text{Si}(111)$, graphene-terminated $6\text{H-SiC}(0001)$, $\text{SrTiO}_3(111)$, $\text{GaAs}(111)$, sapphire(0001), and $\text{InP}(111)$.

Nanowires and nanoribbons of 3D TI materials are of interest because of the peculiar quantum-confined 1D states realized in those structures (Breunig and Ando, 2021). Nanowires of Bi_2Te_3 or similar compounds are usually synthesized by gold-catalyzed vapor liquid solid (VLS) technique (Peng et al., 2010). In this technique, heated Au nanoparticles (typically ~ 20 - nm diameter) are exposed to a flow of the vaporized material, which is absorbed at the top of the melted Au nanoparticles (liquid) and crystallizes at their bottom (solid), resulting in a forest of standing nanowires having a Au nanoparticle at their top.

Interesting phenomena derived from TIs

Topological superconductivity and Majorana zero modes

The spin-momentum locking in the topological surface states of 3D TIs makes them a promising platform to realize topological superconductivity hosting Majorana zero modes (MZMs), which are emergent zero-energy states described by a real creation operator γ . When the creation operator γ of a particle is real, it is self-conjugate, i.e. $\gamma = \gamma^\dagger$, and there is no distinction between creation and annihilation of the particle; in such a situation, one can say that the particle is its own antiparticle, which is the key characteristics of a Majorana particle and γ is called Majorana operator. Importantly, a fermion creation operator $f^\dagger$ can be constructed by using two Majorana operators as $f^\dagger = (\gamma_1 + i\gamma_2)/2$. One can easily see that the number operator of this fermion is written as $f^\dagger f = (1 - i\gamma_1\gamma_2)/2$, which means that $-i\gamma_1\gamma_2$ is 1 (−1) when the fermionic state is occupied (unoccupied). This operator $-i\gamma_1\gamma_2$ is called parity operator, and it signifies the occupancy of the zero-energy fermionic state f by an electron. This situation allows to encode quantum information in terms of the fermion parity by using two MZMs, which is the basis of topological quantum computation (Nayak et al., 2008).

Fu and Kane showed (Fu and Kane, 2008) that when superconductivity is induced in the topological surface states by using the superconducting proximity effect from a conventional s -wave superconductor in contact with a 3D TI, the resulting 2D superconducting state is topological and a MZM will show up in the vortex core. In usual s -wave superconductors, the spin-singlet Cooper pairs always leads to spin degeneracy in the in-gap states created in the superconducting condensate, and the spin degeneracy prohibits in-gap states to have the Majorana character. In the topological surface states, however, the spin-momentum locking removes this degeneracy, and further breaking of time-reversal symmetry in the vortex core leads to the MZM. Nanowires of 3D TIs are also an interesting platform to host MZMs. In this case, the quantum confinement of the topological surface states leads to spin-degenerate 1D subbands, but their degeneracy can be lifted by a parallel magnetic field to recover the spin-momentum locking. When superconductivity is induced in such subbands, 1D topological superconductivity is realized and MZMs will show up at the ends of the nanowire (Cook and Franz, 2011). Further breaking inversion symmetry by electrostatic gating is predicted to give rise to stable MZMs (Legg et al., 2021).

Quantum anomalous Hall effect

The quantum anomalous Hall effect (QAHE) occurs without Landau quantization and it signifies the Chern number of the occupied states of a 2D ferromagnetic insulator. The surface states of 3D TIs can be gapped when time-reversal symmetry is broken

by a ferromagnetic order, which can be induced in 3D TIs by doping magnetic elements. When such a ferromagnetic 3D TI is made into an ultra-thin film (thickness $\lesssim 10$ nm) and the Fermi level is tuned into the gap opened at the Dirac point, the QAHE can be realized. In the QAHE, the electrical current is carried by the spin-polarized 1D chiral edge state, which causes the Hall conductance σ_{xy} to be quantized to e^2/h and the longitudinal conductance σ_{xx} to vanish. Experimentally, the QAHE has been observed in the bulk-insulating TI material $(\text{Bi}_{1-x}\text{Sb}_x)_2\text{Te}_3$ doped with Cr or V (Chang et al., 2013, 2015). It can also be achieved in thin exfoliated flakes of MnBi_2Te_4 (Deng et al., 2020).

When a TI presenting the QAHE is in contact with a conventional s-wave superconductor, the combination of electron doping from the superconductor to the TI surface and the superconducting proximity effect is expected to lead to a time-reversal-breaking 2D topological superconductivity (Qi et al., 2010). The existence of ferromagnetism in the TI surface makes the situation different from the case of the proximitization of a pristine TI. Due to the TRS breaking, the proximitized TI surface is expected to be accompanied by chiral Majorana edge states (Qi et al., 2010), which are a dispersive 1D edge mode having the Majorana character (i.e. this mode is self-conjugate) and may also be called chiral Majorana fermions. Experimentally, the generation of chiral Majorana fermions is yet to be achieved.

Conclusion

The discovery of TIs has caused a paradigm shift in our understanding of how quantum mechanics governs the properties of materials. It has become recognized that the topological nature of the quantum-mechanical wavefunctions realized in a material has sharply observable consequences. The search for new topological invariants in materials and classifications of materials based on new topological classes are an active forefront of the current condensed matter physics. Also, this new viewpoint for materials has triggered the search for similar topological nature in other systems, such as cold atoms, photonic crystals, mechanical metamaterials, qubit arrays, etc.

The concept of topological superconductors is related to topological insulators, because both materials have a gap at the Fermi energy – the superconducting gap in the former and the band gap in the latter. Because of the existence of the gap, the same bulk-boundary correspondence applies to topological superconductors and they must be accompanied by gapless boundary states, which often (but not always) bear the Majorana character. When a 2D topological superconductor breaks time reversal symmetry and has no spin degeneracy, its edge harbors chiral Majorana fermions and the vortex core accommodates a MZM. The 3D TI material Bi_2Se_3 becomes a superconductor upon doping of Cu, Sr, or Nb; the resulting 3D superconductivity has been elucidated to be topological and presents peculiar nematic superconductivity (Yonezawa, 2019). The Majorana physics realized in topological superconductors is a very interesting topic in the future, and TIs provide a useful platform to address topological superconductivity.

Abstract

This article provides a review of methods and results concerning the computation of electronic spectrum for a conductor submitted to a magnetic field.

Key points

- de Haas–van Alphen and Schubnikov–de Haas effects
- Peierls substitution and small magnetic fields
- Harper model and Hofstadter butterfly
- Rotation algebra and analysis tools thereon
- Semiclassical expansion for periodic potentials and strong magnetic fields
- Magnetic operators on triangular and hexagonal lattices
- Helffer and Sjöstrand's semiclassical spectral renormalization scheme

Introduction

A magnetic field applied to the electron gas of a solid breaks the time reversal symmetry giving access to information at the atomic scale that are inaccessible otherwise. The de Haas–van Alphen (de Haas and van Alphen, 1930) oscillations of the magnetic susceptibility or the Shubnikov–de Haas (Schubnikov and de Haas, 1930) oscillations of the conductivity are one of the classical experimental tools used in High Magnetic Fields facilities worldwide to investigate the structure of the Fermi surface. The Hall effect gives access to the type of the charge carriers, electrons, or holes. The cyclotron resonance frequency can also be measured through radio wave oscillations and gives access to the electron effective mass or various relaxation times. At last nuclear magnetic resonance (NMR) experiments give local information on the local density of states.

In most situations, the magnetic field can be considered as uniform at least on the scale of the electron mean free path. In much the same way, it is only at frequencies in the TeraHertz range and beyond, namely, of the order of the inverse of the inelastic collision time, that the magnetic field must be considered as non constant in time. Hence a magnetic field of up to 500T applied during a microsecond (explosion) can still be considered as constant in time.

The energy spectrum of independent electrons in a periodic potential and submitted to a magnetic field was immediately recognized by theoretical Physicists as very difficult to compute. This problem was investigated more systematically from the early 1950s onward. As a consequence of the Peierls approach (Peierls, 1933, 1956), Harper (1955) designed in 1955 a simplified model which is the paradigm of this problem (see Eq. 6). The calculation of the band spectrum of this model was investigated in several papers later on until Hofstadter (Hofstadter, 1976) in 1976 made a numerical computation and showed that it is a remarkable Cantor set (see Fig. 1), at a time when even the word *fractal* had not been coined by Mandelbrot yet. Since then, this *Hofstadter butterfly* has never ceased to fascinate physicists and mathematicians alike, even though it is still difficult to fully observe it in realistic experiments (Ponomarenko et al., 2013; Weiss, 2013). This butterfly has zero Lebesgue measure, namely, it cannot fly (Zero Lebesgue measure means that its surface area is zero. Therefore if it were realized by engineers, the total aerodynamic force acting on the wings would vanish as well, and the butterfly would just not take off.)!

Low magnetic fields

In the simplest approximation, the electron gas in a metal can be seen as a perfect Fermi gas of independent free electrons (or holes) with mass m^* (the effective mass in the medium) and charge $q = \mp e$. Let $\vec{R} = (R_1, R_2, R_3)$ be the position operators and let

Fig. 1 Band spectrum for the Harper model describing a 2D-Bloch electron in a uniform magnetic field (Bellissard, 1994b)(ii).

$\vec{P} = (P_1, P_2, P_3)$ be the momentum operator so that $[R_i, P_j] = i\hbar\delta_{ij}$. The free Hamiltonian is given by $H = \vec{P}^2/2m_*$. Adding a uniform constant magnetic field $\vec{B} = (0, 0, B)$ can be done through the substitution $\vec{P} \rightarrow \vec{P} - q\vec{A}$ if $\vec{A} = (A_1, A_2, A_3)$ is the vector potential, depending upon the position and defined by

$$\partial_1 A_2 - \partial_2 A_1 = B, \quad \partial_2 A_3 - \partial_3 A_2 = 0 = \partial_3 A_1 - \partial_1 A_3.$$

The quasimomentum operator is defined by $\vec{K} = (\vec{P} - q\vec{A})/\hbar = (K_1, K_2, K_3)$ and satisfies the following commutation rules

$$[K_1, K_2] = -i\frac{qB}{\hbar}, \quad [K_2, K_3] = [K_1, K_3] = 0. \quad (1)$$

The Hamiltonian for the free particle in a magnetic field becomes

$$\hat{H}_B = \frac{\hbar^2}{2m_*} (K_1^2 + K_2^2 + K_3^2) = H_B + \frac{\hbar^2}{2m_*} K_3^2.$$

Since K_3 commutes to K_1 and K_2 , it is sufficient to compute the spectrum of H_B . H_B is called the *Landau Hamiltonian* (Landau, 1930) and represents the electronic motion in the plane perpendicular to $\vec{B}$. Thanks to the commutation rules (1), H_B can be seen as an harmonic oscillator with *effective* Planck's constant $\hbar_{\text{eff}} = qB/\hbar$. In particular, its spectrum is made of isolated eigenvalues (called Landau levels)

$$E_n = \hbar\omega_c(n + 1/2), \quad n = 0, 1, 2, \dots \quad \omega_c = qB/m_*.$$

ω_c is called the *cyclotron frequency*. Thanks to the translation invariance of the problem, each such eigenvalue has, however, an infinite multiplicity given by 2π times the number of flux quanta per unit area, namely, $eB/\hbar$.

If the electron gas is now put in a periodic potential $V(\vec{R})$, such as what happens in a real metal, the one-particle Hamiltonian is $\hat{H}_B + V$. Then there are three vectors $\{\vec{a}_1, \vec{a}_2, \vec{a}_3\}$ in $\mathbb{R}^3$ such that $V(\vec{R} + \vec{a}) = V(\vec{R})$ whenever $\vec{a} = m_1\vec{a}_1 + m_2\vec{a}_2 + m_3\vec{a}_3$ and $m_i \in \mathbb{Z}$. If $B = 0$, Bloch's theory (1928) shows that the energy spectrum is made of *bands* described by functions $E_j(\vec{k})$ depending upon the *quasimomentum* $\vec{k}$ and periodic with respect to the reciprocal lattice defined as the set of $\vec{b} \in \mathbb{R}^3$ such that $\vec{a}_i \cdot \vec{b} \in 2\pi\mathbb{Z}$ for $i = 1, 2, 3$. Here, j is the band index and runs in a countable set. If $B \neq 0$ is small enough, the effective Hamiltonian describing

electrons can be obtained from the band functions by substituting $\vec{K}$ to $\vec{k}$ (Peierls substitution [Peierls, 1933](#)). Using the periodicity, each band function can be expanded into a Fourier series

$$E_j(\vec{k}) = \sum_{m \in \mathbb{Z}^3} E_{j,m} e^{i\vec{k} \cdot (m_1 \vec{a}_1 + m_2 \vec{a}_2 + m_3 \vec{a}_3)}, \quad \Rightarrow \quad H_{\text{Peierls}} = \sum_{m \in \mathbb{Z}^3} E_{j,m} e^{i\vec{K} \cdot (m_1 \vec{a}_1 + m_2 \vec{a}_2 + m_3 \vec{a}_3)}, \quad (2)$$

Actually this substitution is only the lowest order contribution to an expansion in powers of B , but the following theorem holds.

Theorem 1 ([Bellissard, 1986](#)). *Let $\hat{H}_{B=0} + V$ have an interval $I \subset \mathbb{R}$ in its spectrum that is disconnected from the rest Γ^c of the spectrum and let I be generated by a finite family $E_1(\vec{k}), \dots, E_N(\vec{k})$ of band functions. Then as $B \neq 0$ is small enough, the gaps separating I from Γ^c does not close. Moreover, the spectrum of $\hat{H}_B + V$ inside this region is described by an effective operator H_{Peierls} of the form given by Eq. (2) where the Fourier coefficients are now $N \times N$ matrices depending continuously of the magnetic field.*

This theorem gives an effective Hamiltonian in terms of a *noncommutative Fourier* expansion using the three unitary operators

$$U_i = e^{i\vec{K} \cdot \vec{a}_i} = (U_i^{-1})^*, \quad U_i U_j = e^{i\theta_{ij}} U_j U_i, \quad \theta_{ij} = -\theta_{ji} = 2\pi \frac{e}{h} \vec{B} \cdot \vec{a}_i \times \vec{a}_j.$$

The angle θ_{ij} represents 2π times the ratio of the magnetic flux through the parallelogram defined by vectors $\vec{a}_i$ and $\vec{a}_j$ by the flux quantum $\phi_0 = h/e$. To complete the analogy with Fourier series, let $\mathcal{T}$ be the linear map defined on the set of polynomials in the U_i 's such that

$$\mathcal{T}(U_1^{m_1} U_2^{m_2} U_3^{m_3}) = 0 \quad \text{if } |m_1| + |m_2| + |m_3| \neq 0 \quad \mathcal{T}(1) = 1. \quad (3)$$

It can be checked that if A, B are two such polynomials, then (a) $\mathcal{T}(A^* A) \geq 0$ (state property), and (b) $\mathcal{T}(AB) = \mathcal{T}(BA)$ (trace property). Moreover it can be shown that $\mathcal{T}$ coincides with the *trace per unit volume* ([Bellissard, 1986](#)), meaning this map generalizes the integration over $\vec{k}$.

For most values (modulus and directions) of the magnetic field $\vec{B}$, the three angles θ_{ij} are incommensurate so that the algebra generated by the U_i 's becomes *simple*, namely, it cannot be decomposed into a direct sum of simpler algebras, making the explicit computation of the energy spectrum a very difficult problem. However, the $\theta_{ij}/2\pi$'s can be seen as dimensionless effective Planck's constant and for a realistic crystal with $|\vec{a}_i| = 1 \text{ \AA}$ and a magnetic field $B = 1 \text{ T}$ their values is $O(10^{-5})$, thus justifying the use of semiclassical methods.

Semiclassical methods and magnetic oscillations

The semiclassical methods go back to the early days of the old theory of quanta, with the Bohr–Sommerfeld (1912–16) quantization formula. The use of such methods for electrons in magnetic fields was the basis of the Onsager argument (1952) ([Onsager, 1952](#)) to explain the de Haas–van Alphen (dHvA) ([de Haas and van Alphen, 1930](#)) and Shubnikov–de Haas (SdH) ([Schubnikov and de Haas, 1930](#)) oscillations ([Lifshitz and Kosevich, 1955](#); [Shoenberg, 1984](#)).

As explained in Section “Low magnetic fields,” the magnetic field B quantizes the quasimomentum space with an effective Planck constant proportional to B . Moreover, if a periodic potential is added, the relevant dimensionless Planck constant is so small as to make the problem semiclassical. In particular, the Heisenberg equations of motions for the effective Peierls Hamiltonian (2) gives

$$\frac{d\vec{K}}{dt} = \frac{1}{\hbar} [H_{\text{Peierls}}, \vec{K}].$$

Since K_3 commutes with K_1 and K_2 , it follows that $dK_3/dt = 0$ so that the motion takes place in the plane perpendicular to $\vec{B}$. Moreover, using the commutation rules (1) leads to the following approximate equation of motion

$$\frac{dk_1}{dt} = -\frac{qB}{\hbar^2} \frac{\partial E_j}{\partial k_2}, \quad \frac{dk_2}{dt} = \frac{qB}{\hbar^2} \frac{\partial E_j}{\partial k_1}, \quad \frac{dk_3}{dt} = 0,$$

implying that $E_j(\vec{k})$ is conserved. Thus the classical orbit associated with conduction electrons in the limit of zero temperature lies on the Fermi surface $E_j = E_F$ in a plane perpendicular to the magnetic field corresponding to $k_3 = \vec{k} \cdot \vec{B} = \text{const}$. Each such plane plays the role of a phase space for one degree of freedom, where k_2 is equivalent to the position and k_1 to the momentum, while the band function $E(k_1, k_2)$ plays the role of the Hamiltonian. Thanks to the Bohr–Sommerfeld quantization formula, only orbits with quantized action do survive quantum interferences, leading to

$$\oint_{\text{orb}} k_1 dk_2 = -2\pi e \frac{B}{\hbar} (n + \nu) \quad n \in \mathbb{Z}, \quad \nu = \text{Maslov index}, \quad (4)$$

Fig. 2 Landau cylinders inside the Fermi surface.

where the contour integral is computed on the classical orbit. By the Stokes formula the *l.h.s.* is the area A enclosed by the classical orbit. The usual argument is now to compute the free energy F of such an electron gas and to remark that it takes into account these orbits with all possible values of k_3 provided $\vec{k}$ stays inside the Fermi surface. The Bohr–Sommerfeld condition (4) select cylinders indexed by n with areas depending on the magnetic field (see Fig. 2).

As the magnetic field increases, the radius of each such cylinders increases as well until it gets out of the Fermi surface. Then the cylinder with index n has an area equal to the maximum area A_{max} of a section of the Fermi surface with a plane perpendicular to the magnetic field. As B increases again, the cylinder with index $n - 1$ dominates leading to oscillations of the free energy with periods given by the Onsager formula

$$\Delta\left(\frac{1}{B}\right) = \frac{2\pi e}{hA_{max}}$$

By tilting the direction of the magnetic field, this formula gives access to measuring the maximal area of the Fermi surface in the plane perpendicular to B . In addition, since the magnetization is given by the thermodynamical relation $M = \mu_0(\partial F/\partial B)_{\mu}$ it also exhibits oscillations at the same period and this is what experiments are measuring giving access to the size of the Fermi surface. Extensions of this theory (the Lifshitz and Kosevich formula (Lifshitz and Kosevich, 1955) and magnetic breakdown) can be found in Shoenberg (1984).

Strong magnetic fields in 2D

If the magnetic field is oriented along one of the crystal axis, the operator U_3 commutes with the others, so the model can be reduced to the 2D plane perpendicular to $\vec{B}$. On the other hand, modern devices that are effectively two-dimensional are currently available in labs. Such is the case for interfaces between the semiconductor and the oxide of a MOSFET or between the two parts of an heterojunction used in meso- or nanoscale technology.

Then, if only one band contributes, two unitaries suffice to express the effective Hamiltonian as

$$H = \sum_{m_1, m_2} \bar{h}_{m_1, m_2} e^{i\theta m_1 m_2 / 2} U_1^{m_1} U_2^{m_2}, \quad U_1 U_2 = e^{i\theta} U_2 U_1, \quad (5)$$

where $\bar{h}_{m_1, m_2} = h_{-m_1, -m_2}$ (selfadjointness of H) are called the *Fourier coefficients* of H . The simplest example is the *Almost–Mathieu model* (if $t_1 \neq t_2$) or *Harper model* (if $t_1 = t_2$) given by

$$H_{Harper} = t_1(U_1 + U_1^{-1}) + t_2(U_2 + U_2^{-1}), \quad (6)$$

where $t_1, t_2 > 0$ are called the *hopping parameters*. A numerical calculation of the band spectrum is possible if $\theta = 2\pi p/q$, where p/q is a fraction. Here is the recipe

(i) replace U_1 and U_2 by $U_i(k_1, k_2) = e^{ik_i} u_i$, where

$$u_1 = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ 1 & 0 & 0 & \cdots & 0 \end{bmatrix}, \quad u_2 = \begin{bmatrix} 1 & 0 & 0 & \cdots & 0 \\ 0 & e^{2i\pi p/q} & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 0 \\ 1 & 0 & 0 & \cdots & e^{2i\pi(p-1)p/q} \end{bmatrix}.$$

Then H becomes a $q \times q$ Hermitian matrix depending periodically on $k = (k_1, k_2)$ with period 2π . Then k is called the *quasimomentum*.

- (ii) For each value of (k_1, k_2) , compute the eigenvalues $e_1(k_1, k_2) \leq \dots \leq e_q(k_1, k_2)$ of $H(k_1, k_2)$. The spectrum is obtained as the union of all these values. In practice the e_j 's are computed for only a finite number of values of (k_1, k_2) . Then, as in the case of band theory, use the symmetries of the model to choose the relevant (k_1, k_2) 's. In the Harper or in the Almost–Mathieu models, the values $(k_1, k_2) = (0, 0)$ or (π, π) gives the band edges.

Fig. 1 represents the energy spectrum of the Harper model (see Eq. 6), which was obtained for the first time in 1976 by D. R. Hofstadter in his Ph.D. thesis (Hofstadter, 1976) as a numerical calculation following the previous algorithm. The vertical axis represents the values of $\theta/2\pi$ between 0 and 1 while the horizontal one represents the values of the energies in unit of $t_1 = t_2$ varying from -4 to $+4$. The picture obtained suggests that the gap edges are continuous with respect to θ even though a closer look shows that these functions have discontinuous derivative at each rational point. This has been proved rigorously (Rammal and Bellissard, 1990; Bellissard, 1994b, a)

Theorem 2. Let H be given by Eq. (5) with Fourier coefficients depending smoothly on θ and decreasing fast enough as (m_1, m_2) increase to infinity. Then the gap edges of the spectrum of H are continuous functions of θ . Moreover, these functions are differentiable almost everywhere. At each rational value of θ , the right and left derivatives of such function exist but are not necessarily equal. The discontinuity of the derivative at a rational point p/q at the edge of the band j , represented by the band function $e_j(k_1, k_2)$, can be computed through the following formula:

$$\Delta = |\det \partial_\mu \partial_\nu e_j(k^{(j)})|^{1/2}$$

where $k^{(j)} = (k_1^{(j)}, k_2^{(j)})$ is the value of the quasimomentum corresponding to the gap edge of the band j .

In the specific case of the Almost–Mathieu operator (see Eq. 6), additional properties have been proved over the years by several theoretical physicists and mathematicians (The number of articles on this subject is too large for being cited here. The main contributors are S. Aubry, D. Thouless, B. Simon, Y. Last, S. Jitomirskaya, and J. Puig.).

Theorem 3. Let H be given by Eq. (6). Then

- (i) for all irrational values of $\theta/2\pi$ and for $t_1 \neq t_2$, the Lebesgue measure of the spectrum of H is equal to $4|t_1 - t_2|$ (Aubry's conjecture).
- (ii) For almost all irrational values of $\theta/2\pi$ and for $t_1 = t_2$, the spectrum of H has zero Lebesgue measure. For a large set of such θ 's, the Hausdorff dimension of the spectrum is less than or equal to $1/2$.
- (iii) If $\theta/2\pi$ satisfies a diophantine condition, then the spectrum of H is a Cantor set (i.e., its complement is a dense open set and it has no isolated points).

Let $\mathcal{T}$ be the trace defined in Eq. (3). Then the integrated density of states (IDoS) $\mathcal{N}(E)$ is defined as the number of eigenvalues of H per unit volume smaller than or equal to E . The Shubin formula asserts that (Bellissard, 1994b)

$$\mathcal{N}(E) = \mathcal{T}(\chi(H \leq E))$$

where $\chi(H \leq E)$ is the projection on the space spanned by eigenstates of H with eigenvalues smaller than or equal to E . Then

Theorem 4. Let H be given by Eq. (5). Then

- (i) its IDoS is a nondecreasing function of E varying from 0 to 1. It is constant of spectral gaps, and its values on spectral gaps are given by the fractional part of $n\theta/2\pi$ from some integer n (gap labeling theorem).
- (ii) If H is the Almost–Mathieu model and if $\theta/2\pi$ is irrational, then for any integer n there is a gap with IDoS equal to the fractional part of $n\theta/2\pi$.

The previous class of model can be seen as a tight-binding representation for the effective Hamiltonian representing the charge carrier motion on a perfect 2D lattice. Other models can be constructed by considering that U_1 and U_2 represent translation along the basis vectors of a 2D crystal. Examples of models are the following:

- (i) The Harper model on a triangular lattice: there are three translations U_1 , U_2 , and U_3 with $U_1 U_2 U_3 = e^{2i\pi\eta}$ and $U_1^{-1} U_2^{-1} U_3^{-1} = e^{2i\pi(\gamma-\eta)}$ if η and $\gamma - \eta$ are the dimensionless fluxes in the two types of triangles (see Fig. 3). The Hamiltonian becomes

$$H_\Delta = t(U_1 + U_1^{-1} + U_2 + U_2^{-1} + U_3 + U_3^{-1}).$$

- (ii) The corresponding model for the honeycomb lattice takes into account the existence of two sublattices A and B (see Fig. 4). Each site in A has its neighbors in B in directions $\vec{e}_1$, $\vec{e}_2$, and $\vec{e}_3$, where these three vectors add up to zero and make angle of 120° and vice versa. Hence a wave packet can be seen as a spinor with components $|\psi_A\rangle$ and $|\psi_B\rangle$ and the Hamiltonian becomes a 2×2 matrix with coefficients depending on the U_i 's as follows

$$H_{\text{hexa.}} = t \begin{bmatrix} 0 & U_1 + U_2 + U_3 \\ U_1^{-1} + U_2^{-1} + U_3^{-1} & 0 \end{bmatrix},$$

Fig. 3 Triangular lattice, its basis, and two types of triangles.

Fig. 4 The honeycomb and its basis.

Here, γ represents the dimensionless flux through the cell generated by $\vec{e}_1$ and $\vec{e}_2$, namely, it is the third of the flux through the unit cell given by an hexagon and $\eta = \gamma/2$.

Various compounds admit a honeycomb structures, such as graphite monolayers built on the surface of silicon carbide SiC. More generally for quasi 2D systems, the previous construction can be used to build the effective Hamiltonian. It has been applied for instance to the magnetic breakdown observed in organic conductors of type (BEDT-TTF), which are mainly a stack of weakly coupled 2D layers (Fortin and Ziman, 1998).

Semiclassical methods at strong magnetic field

It is remarkable then that semiclassical methods could be used at strong magnetic field as well. For indeed, the stronger the magnetic field, the bigger $\hbar_{eff}$. In the eighties, the works by Helffer and Sjöstrand (1987a,b, 1988, 1989, 1990) and Rammal and Bellissard (1990) (Rammal and Bellissard, 1990; Bellissard, 1994b) on the Harper model and its extensions have shown the method.

If θ is close to a rational multiple of 2π , say $\theta = 2\pi p/q + \delta$, with $\delta > 0$ small, then the two unitaries U_1 and U_2 can be taken as $U_i = e^{ik_i} u_i \otimes \hat{U}_i$ with $\hat{U}_1 \hat{U}_2 = e^{i\delta} \hat{U}_2 \hat{U}_1$ implying $U_1 U_2 = e^{i\theta} U_2 U_1$. These unitary operators are $q \times q$ matrices with operator coefficients. The phase factor e^{ik_i} can be chosen arbitrarily, without changing the spectrum. This substitution is the rigorous version of the Peierls one. The following representation is used

$$\hat{U}_i = e^{i\sqrt{\delta} K_i}, \quad K_i = K_i^*, \quad [K_1, K_2] = -i1.$$

Let now $|j\rangle$ denotes an eigenvector of the Hamiltonian obtained by setting $\delta = 0$. Then using the Feshbach method (also called Schur complement or Green function method), the $q \times q$ Hamiltonian H is transformed into a 1×1 effective one given by

$$H_{eff}(z) = \langle j|H|j\rangle + \langle j|HQ_j \frac{1}{z - Q_j H Q_j} Q_j H|j\rangle, \quad Q_j = \mathbf{1}_q - |j\rangle\langle j|.$$

For $\delta = 0$, the Hamiltonian becomes a $q \times q$ -matrix valued function of k denoted by $\mathcal{H}$ while for $\delta \neq 0$, its matrix elements depend on $\hat{U}_1$ and $\hat{U}_2$. It is possible to expand the Hamiltonian in powers of $\sqrt{\delta}$, leading to a generalization of the semiclassical expansion. However here, the Hamiltonian being a $q \times q$ matrix, some complication occurs depending upon what point of the spectrum is considered. The simplest expansion corresponds to expanding near a band edge. Then $k = (k_1, k_2)$ is chosen to correspond to this band edge in the eigenvalue e_j of the Hamiltonian at $\delta = 0$. Moreover, let $|j\rangle$ be the q -dimensional eigenvector of the Hamiltonian for eigenvalue e_j at k . The eigenvalue equation is then $E|\psi\rangle = H_{eff}(E)|\psi\rangle$, which is nonlinear in E . Expanding this operator in powers of $\sqrt{\delta}$ to lowest order gives again an harmonic oscillator as lowest order contribution which can be interpreted as a Landau Hamiltonian.

Using the Landau spectrum, this gives eigenvalues in the following form (see Figs. 5 and 6).

$$E_{n,j}(\delta) = e_j(k) + |\delta|(n + 1/2)(\det D^2 e_j(k))^{1/2} + \delta \frac{\partial e_j(k)}{\partial \delta} + \delta \sigma + O(\delta^{3/2}),$$

where

$$\sigma = \frac{1}{2} \sum_{\ell \neq j} \frac{\langle j|\partial_1 \mathcal{H}|\ell\rangle \langle \ell|\partial_2 \mathcal{H}|j\rangle - \langle j|\partial_2 \mathcal{H}|\ell\rangle \langle \ell|\partial_1 \mathcal{H}|j\rangle}{e_j - e_\ell}$$

The very same formula holds if $\delta < 0$ using a similar method. This formula gives rise to the discontinuity of the derivative of the band edges as stated in Theorem 2. It is remarkable that a systematic higher order expansion gives right corrections to the Landau levels, as long as the level width is ignored.

If two bands are touching (see Fig. 7) for $\delta = 0$, the previous analysis fails. The degeneracy of the eigenvalues e_j and say, e_{j-1} at k for $\delta = 0$ requires using a degenerate perturbation theory. The lowest order in the $\sqrt{\delta}$ expansion is given by a 2D-Dirac operator of the form

$$H_{Dirac} = C, \sqrt{\delta} \begin{bmatrix} 0 & K_1 + iK_2 \\ K_1 - iK_2 & 0 \end{bmatrix} + O(\delta), \quad \Rightarrow \quad E_n^\pm = \pm C\sqrt{n\delta} (1 + O(\delta)),$$

where C is a model-dependent constant, the $E_n^\pm$'s are the eigenvalues, and $n = 0, 1, 2, \dots$ is an integer (see Fig. 8).

As can be seen in Figs. 1, 6, and 8, the Landau-Dirac level broadens into a band as δ gets too large. This is a general phenomena due to *tunneling* in phase space. A spectacular illustration of tunneling effect is the braiding seen in Fig. 9 in the following model:

$$H_2 = t(U_1 + U_1^{-1} + U_2 + U_2^{-1} + \tau(U_1^2 + U_1^{-2} + U_2^2 + U_2^{-2})). \quad (7)$$

Fig. 5 Comparison between semiclassical calculations (continuous lines) and exact numerical spectrum (points) for Landau levels in the Harper model (6) on the square lattice near the band edge at $\theta = 0$ (Bellissard, 1994b)(ii).

Fig. 6 Discontinuity of derivatives of the band edge near the magnetic flux $\alpha = \theta/2\pi \approx 1/3$ for the Harper model on the square lattice (Bellissard, 1994b) (ii).

Fig. 7 Band-touching and bandoverlapping near half-flux in the model $H = U_1 + U_2 + 1/2(U_1^2 + U_2^2) + h.c.$ (Bellissard, 1994b)(ii).

Fig. 8 Comparison between semiclassical calculations (full curves) and exact numerical spectrum (points) for Dirac levels in the Harper model near half flux (Bellissard, 1994b)(ii).

Fig. 9 Spectrum of a Harper-like model (7) for $t_2 = 1/2$. In the left corners, braids are due to tunneling effect (magnetic breakdown) (Bellissard, 1994b; Borelli and Kreft, 1991).

As τ passes beyond the critical value $1/4$, the minimum of energy at zero flux bifurcates to become a local maximum and gives four degenerate minima. If τ is close enough to $1/4$, these four minima are so close that the tunneling effect between them becomes enormous. The semiclassical analysis for the tunneling effect consists in extending the classical motion into the complex values of (k_1, k_2) . Then the classical (complex) action is given by

$$S = \oint_{\gamma} k_1 dk_2,$$

where γ is any path joining two such minima in the complex energy surface $E(k + ik') = E_0$ (if E_0 is the minimum of the energy). Cohomology arguments (Stokes theorem) show that the value of S depends only upon the homotopy class of γ provided it stays in the energy surface. In the previous case, $S = S' + iS''$ with $S' \neq 0$ and $S'' > 0$. Then the splitting between the four-level consecutive to tunneling between the classical minima is proportional to $\Re(\exp i(\phi + S/\delta))$, for some phase ϕ depending upon what splitting is considered, leading to (i) a damping of the amplitude as $\delta \downarrow 0$ given by $e^{-S''/\delta}$ and (ii) an oscillation of the amplitude due to the term $e^{iS'/\delta}$. This is illustrated in Fig. 10 (Barelli and Kreft, 1991).

Fig. 10 Comparison between semiclassical calculations (full curves) and exact numerical spectrum (crosses) for Landau braids of model (7) (Barelli and Kreft, 1991).

Tunneling also explains the broadening of the Landau subbands. For indeed the classical *effective* Hamiltonian obtained for $\delta = 0$ (or for $\theta = 0$ when $p/q = 0$) is a periodic function of the quasi momenta k_1 and k_2 . Thus any band edge occurring at k also occurs at $k + 2\pi(m_1, m_2)$ for all $m_i \in \mathbb{Z}$. Hence, each classical orbit is infinitely degenerate in phase space. Each such orbit represents an approximate eigenstate that can be in principle computed semiclassically and called a *quasimode*. Hence the Hilbert space corresponding to these semiclassical eigenvalues is infinite dimensional, and the tunneling effect between the quasimodes produces a broadening of the Landau or Landau–Dirac levels. As usual with tunneling effect, this broadening is exponentially small in the effective Planck constant (here given by δ). Such a calculation is difficult and many attempts were proposed in the 1960s. Eventually, Helffer and Sjöstrand (1987a,b) carried it out for the special case of the Harper model (Helffer and Sjöstrand, 1988, 1989, 1990) based upon Wilkinson’s analysis (Wilkinson, 1984).

The main result of this analysis is that Landau subbands are well described by an effective Hamiltonian of the form

$$H_{\text{subband}} \stackrel{\delta \downarrow 0}{=} E(\delta) + \left(e^{iS/\delta} (\tilde{U}_1 + \tilde{U}_2) e^{-iS/\delta} (\tilde{U}_1^{-1} + \tilde{U}_2^{-1}) \right) + O(e^{-S_1/\delta}),$$

where $E(\delta)$ is the semiclassical value of the eigenvalue computed by the previous method, t is a model-dependent constant (computable by semiclassical methods), and S is the classical action between two nearest neighboring repetitions of the corresponding band edge in the complex energy surface, $S_1 > |S|$ and

$$\tilde{U}_1 \tilde{U}_2 = e^{i4\pi^2/\delta} \tilde{U}_2 \tilde{U}_1.$$

Hence the spectrum of the subband is itself approximately the same as the Harper spectrum but for a *renormalized* value of the dimensionless flux, namely, $\alpha = \delta/2\pi \mapsto 1/\alpha = 2\pi/\delta$. Since this new flux arises in a phase adding or subtracting an integer to $1/\alpha$ does not change the phase, so that the map becomes $\alpha \in (0, 1) \mapsto G(\alpha) = \{1/\alpha\} \in (0, 1)$, where $\{x\}$ denotes the fractional part of x . G is called the Gauss map and is known to generate the continuous fraction expansion of the number α , namely, if $[x]$ denotes the integer part of x

$$\alpha = \frac{1}{a_1 + \frac{1}{a_2 + \frac{1}{a_3 + \dots}}}, \quad a_n = [G^{n-1}(\alpha)].$$

This rule does not work near a band center though. Then the analysis is more complicated because the classical Hamiltonian associated with the Harper equation has a *saddle point*. Then tunneling between periodic equivalent quasimodes is enhanced by the proximity near a saddle point. Helffer and Sjöstrand showed that depending on the subband considered, there are three types of *normal forms* for the effective Hamiltonian describing them. Moreover, the rule for the new flux might not be given by the Gauss map as was shown by Hofstadter. They also showed that each of them can be analyzed in the same way as the Harper equation so that at each step of the renormalization procedure, the effective subband Hamiltonian takes on one of the four normal forms previously considered: Harper or the three ones occurring at saddle points. Such an analysis explains why the Hofstadter spectrum shown in Fig. 1 (see an enlargement in Fig. 6) looks like a fractal set, namely, it is self-reproducing at any scale.

Abstract

The Ten Martini problem proves, with mathematical rigor, that the energy spectrum for electron on a square or rectangular lattice in a uniform magnetic field is actually a Cantor set whenever the dimensionless magnetic flux per plaquette is irrational. Its enhanced version, sometimes called the Dry Ten Martini problem, is to prove as rigorously that all gaps that may open according to the gap labeling theorem are actually opened. The problem with its main challenges is explained, and its potential relevance in Physics is discussed. Main references for various proofs are provided.

Key points

- Harper model with irrational magnetic fields
- Almost Mathieu operator and Aubry's duality
- Transfer matrix and estimates on gap sizes
- Spectral edges and their continuity
- Cantor nature of the spectrum
- Continued fraction expansions as rational approximations
- Diophantine and Liouville regimes

Introduction

The Ten Martini Problem concerns the simplified, paradigmatic Harper model, representing the movement of a charged quantum particle on a square lattice in the presence of a uniform magnetic field perpendicular to the plane of the lattice. Whenever the flux per unit cell is an irrational multiple of the flux quantum, the numerical calculation performed in 1976 by Hofstadter (1976) (see Fig. 1) suggests that its spectrum is a Cantor set, meaning, in this precise case, that any energy in the spectrum can be approximated by a sequence of energies belonging to a spectral gap, namely, outside the spectrum. This was formulated by Mark Kac as an open problem for mathematicians and made an offer, which is why it was named *Ten Martini*, by Simon (see Simon, 2000, Problem 4):

Prove or disprove that the energy spectrum of the Harper model is a Cantor set for irrational magnetic fields.

Fig. 1 Energy spectrum of the Harper model describing a 2D-Bloch electron in a uniform magnetic field as a function of the dimensionless magnetic flux per unit cell (see Bellissard (1994)(ii)).

The first result was obtained in 1982 (Bellissard and Simon, 1982), but was incomplete. Possible issues showed up with some categories of irrational numbers, and with possible mechanism for gap closing. Several contributions brought critical techniques. The first complete result, described in Section “The Harper and Almost Mathieu models,” was announced in 2006, by Svetlana Jitomirskaya and Artur Avila (Avila and Jitomirskaya, 2006) and published in 2009 (Avila and Jitomirskaya, 2009) in the prestigious journal *Annals of Mathematics*. It took a quarter of a century to solve this difficult problem.

Is this problem relevant for physicists? This was a question posed by Philippe Nozières to the author in the early 1980s during a seminar: “Why should we, physicists, be concerned by the difference between rational and irrational numbers? Isn’t it true that after all, all relevant numbers we use in practice are simple fractions?”. It expressed a deep skepticism toward the content of the talk. The answer is related to the concept of limit, as each irrational number can be seen as a limit of a convergence (or Cauchy) sequence of fractions. There are global (or qualitative) properties seen in the limit that cannot easily be seen before taking the limit. As an analogy, in Statistical Mechanics, one cannot prove the existence of a phase transition without taking the thermodynamic limit, namely, letting the volume of the system be infinite. Only in this limit do we see and classify the phase diagram. Another analogy concerns the distinction between finite sums and integrals: while an integral is defined as a limit of large sum with small summands (Riemann sums), the algebraic treatment of the limit is far easier than treating the sums before taking the limits.

The Harper and Almost Mathieu models

To express the Harper model in a language easily understood by condensed matter physicists, one consider first a 2D-plane and a uniform magnetic field B perpendicular to this plane. A charged particle of charge e and mass m has a kinetic energy $H_L = \hbar^2 (K_1^2 + K_2^2) / 2m$ where $K_i = (p_i - eA_i) / \hbar$ is the wave vector, p_i is the particle momentum operator, and A_i is the magnetic vector potential in the direction $i = 1, 2$. The vector potential is any solution of the equation $(\partial_1 A_2 - \partial_2 A_1) = B$ and the choice of a solution is called a *gauge*. The quantum commutation rule implies

$$[K_1, K_2] = i \frac{eB}{\hbar}, \quad \hbar = \frac{h}{2\pi}. \quad (1)$$

If this particle is forced to stay on a square lattice (in the so-called *tight binding representation*), the translation operators, known as the *magnetic translations* (Zak, 1964a,b), in each of the two directions, are $U_i = \exp(K_i a)$, leading to the tight binding representation

$$H_{AM} = t_1(U_1 + U_1^{-1}) + t_2(U_2 + U_2^{-1}), \quad (2)$$

where t_1 and t_2 are the hopping energies in each direction. The square symmetric case corresponds to $t_1 = t_2$ and is due to Harper (1955a,b) while the rectangular symmetry $t_1 \neq t_2$ will be called the *Almost Mathieu* model here. By a rotation of $\pi/2$, the roles of t_1, t_2 are interchanged while $U_1 \rightarrow U_2$ and $U_2 \rightarrow U_1^{-1}$, but the energy spectrum is unchanged, which will lead to *Aubry's duality*. The remarkable fact is that the two magnetic translations U_1 and U_2 do not commute

$$U_1 U_2 = e^{2i\pi\alpha} U_2 U_1, \quad \alpha = \frac{eBa^2}{h} \quad (\alpha = \text{dimensionless flux}). \quad (3)$$

Indeed, α is the ratio of the magnetic flux Ba^2 through the unit cell and the flux quantum h/e making it a dimensionless parameter.

Definition 1.

- (i) The rotation algebra $\mathcal{A}_\alpha$ is the set of operators that can be approximated by polynomials in U_1 and U_2 for the operator norm.
- (ii) An $*$ -automorphism of $\mathcal{A}_\alpha$ is a linear invertible map $\rho : \mathcal{A}_\alpha \rightarrow \mathcal{A}_\alpha$ respecting the product and taking the adjoint.
- (iii) The spectrum of an element A of $\mathcal{A}_\alpha$ is the set of complex numbers z such that $z - A$ has no bounded inverse. The spectrum is invariant by automorphisms.

It follows that changing U_i into $\epsilon_i U_i$ for $i = 1, 2$ and $\epsilon_i = \pm 1$ does not change the commutation rules, so it defines a $*$ -automorphism that does not change the spectrum of H_{AM} . In particular

The energy spectrum of the Almost Mathieu operator is symmetric around $E = 0$. In addition, it is enough to consider the situation where t_1 and t_2 are nonnegative.

Since the early times of Quantum Mechanics, physicists and mathematicians are usually more comfortable with the Schrödinger equation than dealing with operator algebras. To express it though, the choice of a gauge is required. Two such choices are usually made: the Landau gauge where $A_1 = -By$, $A_2 = 0$ or the symmetric gauge $A_1 = -By/2$, $A_2 = Bx/2$, where (x, y) are the two position coordinates. To take into account the underlying lattice, it will be convenient to write the two coordinates as $x = am$, $y = an$ where m and n are integers (positive or not). The advantage of the Landau gauge comes from its translation invariance in the x -direction. The Schrödinger equation $H\psi = E\psi$ (where E is the energy) becomes

$$\mathcal{E}\psi(m, n) = t_1(e^{2i\pi\alpha n}\psi(m+1, n) + e^{-2i\pi\alpha n}\psi(m-1, n)) + t_2(\psi(m, n+1) + \psi(m, n-1)) \quad (4)$$

An immediate consequence is that if S_1 and S_2 are defined by $S_1\psi(m, n) = (-1)^m\psi(m, n)$ and $S_2\psi(m, n) = (-1)^n\psi(m, n)$, then $S_1 H_{AM}(t_1, t_2) S_1^{-1} = H_{AM}(-t_1, t_2)$ and similarly for S_2 . This shows in a more familiar way that t_1 and t_2 can be chosen positive. Moreover, applying $S_1 S_2$ shows that *the energy spectrum is invariant by $E \rightarrow -E$* .

Due to the translation invariance in the x -direction, it is possible to decompose any eigenstate into plane waves solution of the form $\psi(m, n) = e^{2i\pi\theta m}\phi(n)$, where θ becomes a parameter, leading to

$$E\phi(n) = \phi(n+1) + \phi(n-1) + 2\lambda \cos 2\pi(\alpha n + \theta)\phi(n), \quad \lambda = \frac{t_1}{t_2}, \quad E = \frac{\mathcal{E}}{t_2}. \quad (5)$$

The latter expression explains the name *Almost Mathieu* given to the model (a suggestion of Barry Simon): it is a discrete and almost periodic version of the Mathieu equation (second-order differential equation with a periodic cosine potential). Indeed here, the ratio α measures the incommensurability between the periodicity of the cosine potential and the periodicity of the 1D-lattice labeled by n . It ought to be remarked also that both E and λ are dimensionless parameters that will nevertheless be called *energy* and *coupling constant*, respectively. At last by imposing a rotation of $\pi/2$ in the original lattice, exchanging the roles of t_1 and t_2 , it leads to Aubry (1978) and Aubry and André (1980).

Proposition 1 (Aubry's duality). *The energy spectrum of the Almost Mathieu operator is unchanged under the transformation of (λ, E) into $(1/\lambda, E/\lambda)$.*

The main result obtained by Avila and Jitomirskaya requires the concept of Cantor set. Mathematically it is defined as a topological compact set completely disconnected with no isolated point. For physicists, compactness is not a familiar concept; it actually means that a compact set can be approximated by a finite number of points. More precisely if, for instance, the topology is defined by a metric, then given any $\varepsilon > 0$, there is a finite family of points $\{x_1, x_2, \dots, x_n\}$ such that the balls of radius ε centered at these points cover the set.

More concretely, if K is a Cantor subset of the real line $\mathbb{R}$, then (i) it is closed, namely, any convergent sequence of real numbers in K converges, in K , (ii) it is contained into a closed interval of finite length, (iii) its complement $\mathbb{R} \setminus K$, which is open, is dense in $\mathbb{R}$, namely, any real number can be approximated by a sequence of numbers outside K (iv) for all points x in K and any $\varepsilon > 0$, the interval $(x - \varepsilon, x + \varepsilon)$ intersects K (namely no point is isolated).

With this in mind, the main result can be phrased as follows:

Theorem 1 (Ten Martini (Avila and Jitomirskaya, 2009)). *The energy spectrum of the Almost Mathieu operator is a Cantor set for any irrational value of α and non zero value of λ .*

The following sections will describe more about the sources of difficulties and the strategy of the proof.

Numerical solution

In order to solve Eq. (5), the first step consists in assuming α rational, namely, of the form $\alpha = p/q$ where p and q are integers prime to each other (irreducible fraction). Then, the potential part has period q . Therefore, following Bloch's theory, one searches for solutions satisfying $\phi(n+q) = e^{ik_1} \phi(n)$ for any n . The set of such sequences becomes a Hilbert space of finite dimension q when endowed with the inner product $\langle \psi | \phi \rangle = \sum_{n=0}^{q-1} \overline{\psi(n)} \phi(n)$. Hence, the problem is amenable to numerical calculation as the Hamiltonian becomes a finite dimensional matrix. At that point there are two ways of seeing this problem: (i) by writing down this $q \times q$ matrix and finding solution of the characteristic polynomial and (ii) by exploiting the two-term recursion character of Eq. (5) and use transfer matrix. Numerically the method (ii) is faster while method (i) gives useful qualitative and quantitative information.

Transfer matrix

For numerical efficiency, it is actually more convenient to use the transfer matrix formulation. Namely, the wave function ϕ is written through a 2D vector $\Phi(n)$ with components $\phi(n)$, $\phi(n-1)$. Then Eq. (5) becomes

$$\Phi(n+1) = S(n)\Phi(n), \quad S(n) = S(E, \lambda; nx + \theta) = \begin{bmatrix} E - 2\lambda \cos 2\pi(\alpha n + \theta) & -1 \\ +1 & 0 \end{bmatrix}. \quad (6)$$

An important property is $\det S(n) = 1$, in particular $S(n)$ is invertible. For $\alpha = p/q$, an irreducible fraction, S , is periodic, namely, $S(n+q) = S(n)$. Bloch's theory leads to searching solutions such that $\Phi(n+q) = e^{ik} \Phi(n) = T(n)\Phi(n)$, using the recursion formula with $T(n) = \prod_{m=0}^{q-1} S(m+n)$ (ordered product: m increases from right to left). Hence e^{ik} is an eigenvalue of the 2×2 matrix $T(n)$. Since $\det T(n) = 1$, it follows that the other eigenvalue is e^{-ik} so that $\text{Tr}(T(n)) = 2 \cos k \in [-2, +2]$. Such a condition is satisfied only if E belongs to the energy spectrum Σ . The trace of $T(n)$ is a monic polynomial of degree q with respect to E (namely, its highest degree coefficient is 1). Moreover, since all $S(n)$ s are invertible, it follows that $T(n+1)$ is similar to $T(n)$ so that $\text{Tr}(T(n))$ is independent of n . However, changing n into $n+1$, is equivalent to changing θ into $\theta + p/q$. Consequently $\text{Tr}(T(n))$ is periodic of period $1/q$ with respect to θ so that it is a Fourier series in the variable $e^{2i\pi q\theta}$. But each matrix $S(n)$ is a trigonometric polynomial of degree ± 1 in $e^{2i\pi\theta}$ so that $T(n)$ has degree ± 1 in $e^{2i\pi q\theta}$, leading to the first *Chambers formula* (see [Chambers, 1965](#), Appendix)

$$\text{Tr}(T(n)) = P_\lambda(E) + (-1)^q 2\lambda^q \cos 2\pi q\theta. \quad (\text{Chambers '65}) \quad (7)$$

It follows that eigenvalues are given by the equation

$$P_\lambda(E) = 2 \cos(qk) - (-1)^q 2\lambda^q \cos 2\pi q\theta. \quad (8)$$

Varying k and θ gives the band spectrum. In particular $E \in \Sigma$ if and only if $P_\lambda(E) \in [-2(1+\lambda^q), +2(1+\lambda^q)]$. This is seen in [Fig. 2](#) for q even. It follows that the band edges are given by the values $(qk, 2\pi(q\theta + 1/2)) = (0, 0)$ or (π, π) so that numerically there is no need to explore all these values. This is the algorithm used since the work of [Hofstadter \(1976\)](#).

[Fig. 1](#) is obtained this way with α on the vertical axis and E on the horizontal axis for the value $\lambda = 1$ corresponding to the square symmetry.

Fig. 2 Construction of the band spectrum from Chamber's formula.

Studying the mathematical properties of the transfer matrix was a central theme for Avila and Jitomirskaya. Their proof of the Ten Martini problem is based upon this point of view.

From these arguments, it follows that the transfer matrix method gives all useful spectral information on the Almost Mathieu model. It is important to notice though, that for this method to be useful, the Schrödinger equation must be reducible to a 2-term recursion formula. However, for the purpose of physical applications, it is inconvenient. Indeed, the effective Hamiltonian describing an electron on a square lattice defined by a periodic potential, once expressed in the tight binding representation, is never the Almost Mathieu model, but a small perturbation of it, including higher powers of u_1 and u_2 . In such a case, the transfer matrix formulation is no longer appropriate.

Matrix formulation

Looking back at the Schrödinger point of view, it is convenient to set $\varphi(n) = e^{-ik_1} \phi(n)$, with $k_1 = k$, so that φ is periodic with period q . Hence ϕ can be seen as a complex vector with q components. In addition, it is convenient to write $k_2 = 2\pi\theta$. With such notations, let u_1 denote the translation operator $u_1\varphi(n) = \varphi(n-1)$ and let u_2 denote the multiplication operator $u_2\varphi(n) = e^{2i\pi np/q} \varphi(n)$. Then u_1 and u_2 can be seen as $q \times q$ matrices such that the monomials $u_1^{m_1} u_2^{m_2}$ make up a basis of the space of $q \times q$ matrices. Then

$$u_1 u_2 = e^{2i\pi p/q} u_2 u_1, \quad u_i^{-1} = u_i^*, \quad u_1^q = u_2^q = 1. \quad (9)$$

In addition, using the Hilbert–Schmidt inner product of two $q \times q$ complex matrices a and b defined by

$$\langle a|b \rangle = \frac{1}{q} \text{Tr}(a^* b), \quad (10)$$

the basis $\{u_1^{m_1} u_2^{m_2} ; 0 \leq m_i \leq q-1\}$ is *orthonormal* and *complete* in the set of $q \times q$ complex matrices (this can be called *noncommutative Fourier expansion*).

Using these notations, it follows that Eq. (5) becomes

$$H(k_1, k_2)\varphi = E\varphi, \quad H(k_1, k_2) = e^{ik_1} u_1 + e^{-ik_1} u_1^{-1} + \lambda(e^{ik_2} u_2 + e^{-ik_2} u_2^{-1}). \quad (11)$$

Then the eigenvalues of $H(k_1, k_2)$ are the roots of $z \rightarrow P(z, k_1, k_2) = \det(z - H(k_1, k_2))$, which is a monic polynomial of degree q in z , and trigonometric polynomial of degree at most q and at least $-q$ in each of the k_i 's. Using the commutation rules given in Eq. (9), and the invariance of the determinant under unitary transformation u_i 's, it follows that P is actually periodic of period $2\pi p/q$ in each of the k_i , namely, periodic of period $2\pi/q$ since p/q is irreducible. Using the Fourier expansion in the k_i 's, a simple calculation leads to (see Chambers, 1965, Appendix; Chambers used the transfer matrix formulation)

$$P(z, k_1, k_2) = P_\lambda(z) - 2(\cos(qk_1) + \lambda^q \cos(qk_2)), \quad (\text{Chambers '65}) \quad (12)$$

where P_λ is also a monic polynomial of degree q in z and a polynomial in λ of degree q as well. Comparing with Eq. (8), it is clear that the two polynomial P_λ must be the same. Since $H(k_1, k_2)$ is Hermitian, the equation $P(z, k_1, k_2) = 0$ has q real roots in z for each value of k_1 and k_2 . In particular, it follows that the band spectrum is defined by the values of z (automatically on the real line) for which $-2(1 + \lambda^q) \leq P_\lambda(z) \leq +2(1 + \lambda^q)$. It follows that P_λ is monotonous on each band.

If q is *odd*, changing k_i into $k_i + \pi$ changes the sign of $H(k_1, k_2)$. From this it follows that $P_\lambda(-z) = -P_\lambda(z)$ is odd. Therefore $P_\lambda(0) = 0$. In particular if k_1 and k_2 are chosen such that $2\cos(qk_1) + \lambda^q 2\cos(qk_2) = 0$, it follows that 0 is an eigenvalue. Thus 0 belongs to the spectrum of the Almost Mathieu operator for any odd value of q .

If q is *even*, the unitary matrix $S = u_1^{q/2} u_2^{q/2}$ gives $SH(k_1, k_2)S^{-1} = -H(k_1, k_2)$. From this it follows that the set of eigenvalues of $H(k_1, k_2)$ is invariant under $E \rightarrow -E$. Moreover $P_\lambda(-z) = P_\lambda(z)$ follows from this symmetry. It follows that when q is a multiple of 4, $z = 0$ is a maximum of P_λ ; therefore it is enough to look at k_i 's such that $qk_i = 0 \pmod{2\pi}$. If $q - 2$ is a multiple of 4, it is a minimum of P_λ instead, and it is enough to look at k_i 's such that $qk_i = \pi \pmod{2\pi}$. In addition the symmetry $R\varphi(n) = \varphi(-n)$ leaves the matrices $H(k_1, k_2)$ invariant for the values of (k_1, k_2) at these extrema. By decomposing the space into the direct sum of subspaces of symmetric or antisymmetric eigenvectors of R , a simple counting leads to

Proposition 2 (see Bellissard and Simon, 1982). *The spectrum of the Almost Mathieu operator is symmetric around $E = 0$ and $E = 0$ always belongs to this spectrum for any fractional value of α . The band edges are given by the eigenvalues of $H(k_1, k_2)$ for which $k_i = 0 \pmod{\pi}$. In addition if $\alpha = p/q$ with q odd, $E = 0$ is the center of the middle spectral band while if q even, the central gap is closed, namely, the two neighboring spectral bands are touching.*

Gap opening

Even for $\alpha = p/q$ is an irreducible fraction, the question of showing that the spectral bands are separated by a gap is nontrivial. It boils down to showing that for the edges, values of (k_1, k_2) the roots of $P_\lambda(z) = \pm 2(1 + \lambda^q)$ are simple. Let then Σ_λ denote the set of pairs (z, λ) such that $P(z, 0, 0) = 0$ or $P(z, \pi, \pi) = 0$. Since P depends polynomially on λ as well, Σ is a finite union of (algebraic) curves. The condition of $z = a$ being a double root of this equation boils down, thanks to Eq. (12) to add the condition $dP_\lambda/dz(z = a) = 0$. In the curve $\Sigma - \lambda$, such a condition is satisfied only at a finite number of isolated points because of the polynomial character of all these equations (Bellissard and Simon, 1982). In particular, the complement of the union of these points in the plane (z, λ) , which corresponds to gap opening, is a dense open set $\mathcal{O}(\alpha)$. The intersection $\mathcal{O} = \cap_{p/q} \mathcal{O}(p/q)$ might not be open but is called a G_δ -set

(countable intersection of open sets). Using a fundamental standard result of Baire, since each term of the intersection is dense, the set $\mathcal{O}$ is dense as well. Mathematicians are calling a property *generic* whenever it holds true on a dense G_δ -set. Using this argument, and extending it to include irrational values of α , a first weak form of the Ten Martini problem was proved in Bellissard and Simon (1982)

Proposition 3. *For a generic set of values of $(\alpha, \lambda) \in \mathbb{R}^2$, the spectrum of the Almost Mathieu model is a Cantor set.*

As it turns out, Choi, Elliott, and Yui proved a stronger result in a remarkable paper (Choi et al., 1990), using a purely algebraic method.

Theorem 2 (see Choi et al., 1990). *For $\alpha = p/q$, an irreducible fraction, and $\lambda \neq 0$ there are constants $c_0(\lambda) > 0$ and $1 > c_1 > 0$ such as all gaps of H_{AM} , except at $E = 0$, have width at least $c_0(\lambda) (c_1 \lambda)^{q/2}$. In particular all gaps but for $E = 0$ are open.*

In particular this proves that all gaps but the central one are open, and it gives a quantitative estimate. The method relies upon a remarkable Gaussian formula, namely

$$(u_1 + \lambda u_2)^n = \sum_{j=0}^n \frac{[n]_\zeta}{[j]_\zeta [n-j]_\zeta} \lambda^j u_1^{n-j} u_2^j, \text{ where } [n]_\zeta = \prod_{j=1}^n (1 - \zeta^j), \zeta = e^{2\pi i \alpha}. \quad (13)$$

The first main result consists in evaluating the Gaussian binomial coefficient for $n = 2j$ and they proved, using an easy computation, that because $\zeta^q = 1$,

$$\frac{|[2j]_\zeta|}{|[j]_\zeta|^2} \geq 1. \quad (14)$$

Next step: If f is any monic polynomial of degree $2m < q$, the development of $f(H(k_1, k_2))$ in powers of u_1 and u_2 (noncommutative Fourier expansion), the term $u_1^m u_2^m$ can only come from the expression $(e^{ik_1} u_1 + \lambda e^{ik_2} u_2)^m$ the coefficient of which is the product of λ^m by the Gaussian binomial coefficient corresponding to $n = 2m$, $j = m$. Using the inequality (14), this coefficient is larger than or equal to λ^m . On the other hand, this coefficient is given by (see Eq. (10) and the following comment)

$$\lambda^m e^{im(k_1 + k_2)} \frac{[2m]_\zeta}{[m]_\zeta^2} = \frac{1}{q} \text{Tr}(u_2^{-m} u_1^{-m} f(H(k_1, k_2))) \quad (15)$$

The right-hand side is bounded from above by $\|f(H(k_1, k_2))\|$ while the left hand side is bounded from below by λ^m , leading to

$$\|f(H(k_1, k_2))\| \geq \lambda^m. \quad (16)$$

The next and last step consists in applying this result to various f 's. For instance, if $\lambda \leq 1$ and $q = 2m + 1$ then choose $1 \leq j \leq q$. Set $f_j(x) = \prod_{i: i \neq j} (x - E_i)$ whenever $E_1 \leq E_2 \leq \dots \leq E_q$ denotes the eigenvalues of $H(k_1, k_2)$ (see Fig. 2). Then f_j is monic of degree $2m < q$ and $f_j(H(k_1, k_2)) = \prod_{i: i \neq j} (E_j - E_i) \times |j\rangle \langle j|$ where $|j\rangle$ is the eigenstate of $H(k_1, k_2)$ for the energy E_j . Since $|E_j - E_i| \leq 4(1 + \lambda^q) \leq 8$, combining with Eq. (16), this gives

$$|E_{j+1} - E_j| \geq \frac{\lambda^{(q-1)/2}}{8^{q-2}}. \quad (17)$$

A similar bound is obtained for $\lambda \geq 1$ using Aubry's duality. For $q = 2m + 2$, a similar strategy can be used, exploiting the fact that each eigenvalue E has also $-E$ as an eigenvalue. However the eigenvalues of the two central bands are to be excluded from the polynomial f since the central gap is actually closed.

A toolbox for solving the Ten Martini problem

The main problem with the Hofstadter spectrum shown in Fig. 1 is that even if it looks like having global properties of a fractal, with gap boundaries looking regular as a function of α , it is computed only for a finite number of rational values of α . Does it guarantee that this picture still holds for irrational values? So far there is no finite algorithm allowing to compute the energy spectrum of the Almost Mathieu model with α irrational. Physicists are pragmatic: if irrational values of α were showing unexpected properties, it would be seen for rational numbers p/q with large q 's. They just let Mathematicians play with the problem. As it turns out, going from fractions to irrational numbers is technically very demanding. No wonder that it took a quarter of a century (Avila and Jitomirskaya, 2006, 2009) to solve this problem entirely. It required the contributions of two of the finest analysts in the world, one of whom is a Fields medalist, to achieve such a difficult task. But several contributions brought some key arguments used in the final proof, the list of which can be found in Last (2005).

The main steps leading to the final result are

1. controlling the rational approximations of α ,
2. controlling the gap edges continuity as a function of α ,
3. evaluating the size of gaps for rational values of α .

Rational approximation

The traditional description of numbers by decimal expansion gives approximation by decimal fractions. Binary expansion achieves similar results but with only two digits. However these expansions are not necessarily optimal to control the approximation of a number by fraction. The continued fraction expansion described in this section was introduced a long time ago in history, but two names emerge who provided substantial general results, namely, Euler in 1737 and Gauss in 1813. Both used continued fractions to express special functions from which a formula for special numbers can be derived. A classical introduction, actually easy to read, can be found in the book (Hardy and Wright, 2008), by Hardy and Wright (see Chapters 10 and 11).

Given a real number $0 < \alpha \leq 1$, it has a positive inverse $1/\alpha > 1$ so that it can be written in a unique way as $1/\alpha = a_1 + \alpha_1$ where $a_1 = [1/\alpha]$ is a natural integer (in particular $a_1 \geq 1$) called the *integer part* and $0 \leq \alpha_1 = \{1/\alpha\} < 1$ is the *fractional part* of $1/\alpha$. This means

$$\alpha = \frac{1}{a_1 + \alpha_1}.$$

If $\alpha_1 \neq 0$, applying the same procedure with α_1 and iterating leads to the continued fraction $\alpha = [a_1, a_2, a_3, \dots]$ where

$$\alpha = \frac{1}{a_1 + \frac{1}{a_2 + \frac{1}{a_3 + \dots}}} \quad \text{denoted by} \quad \alpha = [a_1, a_2, a_3, \dots], \quad (18)$$

where a_i are all natural integers. If α is a fraction, this procedure stops after a finite number of steps. In any case, stopping the fraction at level n gives a fraction denoted as $p_n/q_n = [a_1, a_2, a_3, \dots, a_n]$ which satisfies $q_{n+1} = a_{n+1}q_n + q_{n-1}$, $p_{n+1} = a_{n+1}p_n + p_{n-1}$ with initial conditions $q_0 = p_1 = 1$. It is easy to check by induction that $q_{2m}p_{2m-1} - q_{2m-1}p_{2m} = 1$ for m a natural integer and that

$$\frac{p_{2m}}{q_{2m}} < \alpha < \frac{p_{2m-1}}{q_{2m-1}}, \text{ for } m \geq 1 \quad \Rightarrow \quad \left| \alpha - \frac{p_n}{q_n} \right| < \frac{1}{q_n q_{n+1}}, \quad \forall n \geq 1.$$

In particular, since $q_{n+1} \geq q_n + q_{n-1}$, it implies that the q_n 's increase exponentially fast in n and that the continued fraction actually converges. One can then classify numbers according to how fast this expansion converges.

If one endows the interval $[0, 1]$ with uniform probability, the following holds:

1. If $\alpha = [a_1, a_2, \dots, a_n, \dots]$, the sequence $(a_n)_{n \geq 1}$ is unbounded with probability one.
2. Given $\eta > 0$, with probability one, there is $c > 0$ such that $|\alpha - p/q| \geq c/q^{2+\eta}$, which implies that $q_{n+1} \leq c^{-1}q_n^{1+\eta}$. Such numbers are called *Diophantine*.

Among the non-Diophantine numbers, there are two categories, the ones slowly approximated by rationals and the ones that are extremely well approximated by rationals which are called *Liouville numbers*. Hence, numbers $0 \leq \alpha \leq 1$ with bounded sequence of a_n (such as the golden mean $\sigma = (\sqrt{5} - 1)/2$ for which $a_n = 1$ for all n 's) are those that are the most difficult to approximate by fractions. Their set has zero probability, but is nevertheless a dense G_δ , namely, it is uncountably infinite or they are *generic*. Similarly, numbers such that $q_{n+1} \geq f(q_n)$ for infinitely many n 's for some function f increasing faster than any polynomial at infinity have also zero probability even if they make a G_δ -set.

In their seminal work (Avila and Jitomirskaya, 2006), Jitomirskaya and Avila used the following measure of the speed of convergence, namely, they define

$$\beta = \limsup_{n \rightarrow \infty} \frac{\ln q_{n+1}}{q_n}.$$

If $0 < \beta < \infty$, then it means roughly that given $0 < \beta' < \beta$, the inequality $q_{n+1} \geq e^{\beta' q_n}$ holds for infinitely many n 's. Moreover, if $\beta' > \beta$ then there is an integer N such that $q_{n+1} \leq e^{\beta' q_n}$ for $n \geq N$. Such numbers are Liouville.

Indeed Liouville proved in the mid-19th century that if α is algebraic and irrational, namely, if it is the root of a polynomial of degree l with integer coefficients, then there is a constant $C > 0$ such that $|\alpha - p/q| \geq C/q^l$ for any fraction. In particular algebraic numbers are Diophantine and have $\beta = 0$. This theorem allowed Liouville to exhibit nonalgebraic irrational numbers, namely, transcendental numbers, for the first time. His method was used, improved and optimized over the decades, and permitted eventually to prove that both numbers e and π were transcendental.

Spectral continuity

Looking back at the Hofstadter spectrum in Fig. 1, it seems that the gap edges vary continuously with α . But it cannot be a proof since the bands represented in this figure correspond to rational values of α . Mathematicians must prove that property. The earliest result goes back to 1982 (Elliot, 1982) and 1983 (Avron and Simon, 1983), showing that the gap edges are continuous indeed. However to make sure that the gap width does not change wildly, simple continuity is insufficient.

In order to describe the main result, let f be a function defined on the real line with real values. Let also $0 < r \leq 1$. The function f is called r -Hölder continuous on an interval (a, b) if there is a constant $C > 0$ such that for any pair of points $a < x, y < b$ in this interval, $|f(x) - f(y)| \leq C|x - y|^r$. If $r = 1$ the function f is called Lipschitz continuous. The best result known so far is the following:

Theorem 3. For $0 \leq \alpha \leq 1$, let $H_\alpha = U_1 + U_1^{-1} + \lambda(U_2 + U_2^{-1})$ denote the Almost Mathieu operator (see Eq. 2 with $t_1 = 1$, $t_2 = \lambda$), where U_1 and U_2 generate the irrational rotation algebra $\mathcal{A}_\alpha$ (see Eq. 3).

- (i) If $\mathfrak{g}_\alpha = (E_-(\alpha), E_+(\alpha))$ is a gap in the spectrum of H_α , the gap edges $E_\pm(\alpha)$ are Lipschitz continuous functions of α on every interval where the gap does not close. The same holds for the spectral boundaries.
- (ii) In the vicinity of a value α_0 for which the gap closes, namely, $E_+(\alpha_0) = E_-(\alpha_0)$, the gap edges are $1/2$ -Hölder continuous.

Several proofs are available in the literature, all technical. In particular, a general argument valid for any self-adjoint operator can be found in Beckus and Bellissard (2016). But the reference used by Avila and Jitomirskaya is (Avron et al., 1991) the oldest. This result is actually optimal: Lipschitz continuity cannot be replaced by differentiability. Indeed the right and left derivatives exist everywhere, but they do not coincide at any rational value of α (Rammal and Bellissard, 1990). In addition, the central gap of the Almost Mathieu operator for $\alpha = p/q$ with q even is closed. A semiclassical expansion of the gap edge (Rammal and Bellissard, 1990) confirms that the nonvanishing gap edges are proportional $\sqrt{\alpha - p/q}$ in the vicinity of $\alpha_0 = p/q$ (see Fig. 1 especially at $\alpha_0 = 1/2$).

Transfer matrices and gaps

Avila and Jitomirskaya used the transfer matrix method. They followed a strategy initiated by Puig (2004) and Eliasson (1999). Here are few hints about how to use it to prove that all but the central gap of the Almost Mathieu spectrum are open.

Rotation number

As described in Eq. (6), the Schrödinger equation for the Almost Mathieu model can be expressed as

$$\Phi(n+1) = \begin{bmatrix} \phi(n+1) \\ \phi(n) \end{bmatrix} = S(E, \lambda; \alpha n + \theta) \Phi(n)$$

where $S(E, \lambda; x)$ is a 2×2 matrix with real coefficients and determinant 1. It is a trigonometric polynomial in x of period 1. Since $\Phi(1) \neq 0$, the vector $\Phi(n)$ never vanishes as n varies. Therefore the straight line passing through 0 and $\Phi(n)$ rotates in the 2D plane. This straight line is the same after a rotation by π of course. After N such rotations, if $\pi\theta_N$ denotes the total angle between $n = 1$ and $n = N$ seen as a real number defines a rotation angle per step namely

$$\rho(E, \lambda) = \lim_{N \rightarrow \infty} \frac{\theta_N}{N}, \quad (\text{rotation number}) \quad (19)$$

Actually, at each rotation of π , the wave function $\phi(n)$ changes its sign so that this rotation number coincides with the number of sign changes of ϕ per unit length. This is a critical concept exhibited in the 19th century, known as the Sturm–Liouville theory, for second-order differential equations, permitting to relate the rank of excited states energies, ranked in increasing order starting at 0 for the ground state to the number of zeroes of the corresponding wave eigenfunction. Using this method for the Almost Mathieu operator restricted to a finite interval with N sites permits to define the number of eigenstates below some energy E per unit length to give the *integrated density of states* (IDS) $\mathcal{N}(E, \lambda)$. By a classical argument using the Sturm–Liouville theory, the rotation number and the IDS are simply related by

$$\rho(E, \lambda) = \mathcal{N}(E, \lambda).$$

In particular if E belongs to a spectral gap, these numbers do not depend upon where in this gap E is located since changing E in this gap does not add any new eigenstate. Using various arguments, topological (K -theory) or analytical, each with different flavor (see Bellissard, 1982; Johnson and Moser, 1983; Elliot, 1982), it can be shown that

Theorem 4 (Gap Labeling Theorem). *Given a spectral gap $\mathfrak{g}$ of the Almost Mathieu operator, there is an integer m such that $N(E, \lambda) = m\alpha - \lfloor m\alpha \rfloor$ for $E \in \mathfrak{g}$.*

This result is not surprising for a physicist. Indeed, it is sufficient to consider the fractional situation with $\alpha = p/q$. Gaps separate Bloch bands. Therefore if E belongs to such a gap, the number of eigenstates per period below this energy is one per band below this gap and each band count for the fraction $1/q$ of the total number of eigenstates per period. Since p/q is irreducible, this number is a multiple of $\alpha = p/q$ modulo 1. Unsurprisingly, the Gap Labeling Theorem extends this result to irrational values of the dimensionless magnetic flux per unit cell. But as usual, the proof requires more than just such an argument.

Floquet–Bloch solutions

The next step is to find solutions of Bloch type, called *Floquet solutions* in Mathematics. In general a Floquet–Bloch solutions should have the form $\phi(n) = e^{-ikn} \varphi(n\alpha + \theta)$, where k is equal to the parameters k_1 in Eq. (11). Whenever α is irrational, the Almost Mathieu spectrum does not depend upon these parameters so that k can be chosen to be zero. Hence a Bloch wave solution has the form $\phi(n) = \varphi(n\alpha + \theta)$ with φ a smooth function with period 1. The Schrödinger equation takes the form

$$\varphi(x - \alpha) + \varphi(x + \alpha) + 2\lambda \cos x \varphi(x) = E\varphi(x) \quad (20)$$

By Fourier's expansion, the Fourier coefficients $\hat{\varphi}(l)$ satisfy the *dual equation* (Aubry and André, 1980) called *Aubry's duality*

$$\hat{\varphi}(l-1) + \hat{\varphi}(l+1) + \frac{2\cos(2\pi l\alpha)}{\lambda} \hat{\varphi}(l) = \frac{E}{\lambda} \hat{\varphi}(l) \quad (21)$$

At this point if we impose to search φ to be only square integrable in x over intervals of length 1, the Fourier series must be square summable, implying that $\hat{\varphi}(l) \rightarrow 0$ as $l \rightarrow \pm\infty$. The following Wronskian argument implies that if such an L^2 Floquet–Bloch solution exists, it must be unique, up to a scaling factor: assume that $\hat{\varphi}, \hat{\psi}$ are to square-summable solutions of Eq. (21). Then the Wronskian is given by

$$W(n) = \begin{bmatrix} \hat{\varphi}(n) & \hat{\psi}(n) \\ \hat{\varphi}(n-1) & \hat{\psi}(n-1) \end{bmatrix}.$$

It clearly satisfies

$$S(n)W(n) = W(n+1), \quad S(n) = \begin{bmatrix} E/\lambda - 2\cos(2\pi l\alpha) & -1 \\ 1 & 0 \end{bmatrix}.$$

The property $\det S(n) = 1$ implies $\det W(n) = \det W(n-1) = \text{const.}$ As both $\hat{\varphi}$ and $\hat{\psi}$ decay to zero as $n \rightarrow \pm\infty$, by assumption, it follows that $\det W(n) = 0$ for all n 's implying that $\hat{\varphi} = c\hat{\psi}$ are proportional, c being a scalar independent of n .

Reducibility to constant coefficients

Reducibility was introduced by Eliasson (1999). It consists in finding a constant 2×2 matrix B of determinant 1, called the *Floquet matrix* and an x dependent smooth 2×2 matrix Z , of period 1 and determinant 1, such that

$$S(E, \lambda; x) = Z(x + \alpha)BZ(x)^{-1}. \quad (\text{reducibility}) \quad (22)$$

If a smooth Floquet solution exists then the vector $\Phi(n)$ can be written as $\Phi(n) = \Psi(n\alpha + \theta)$ for $\Psi(x)$ smooth and periodic of period 1. Then setting $\hat{\Psi}(x) = Z(x)^{-1}\Psi(x)$ leads to

$$\hat{\Psi}(x + \alpha) = B\hat{\Psi}(x).$$

Iterating implies, since $\hat{\Psi}$ is smooth and periodic, that B^n must stay bounded as $n \rightarrow \pm\infty$. In particular its two eigenvalues must have modulus smaller than or equal to one. Since the determinant is 1, the eigenvalues are inverse of each other so that they must be of the form $e^{\pm i\gamma}$ for some angle γ . In particular if $\gamma \notin \{0, \pi\}$, it would give two coexisting Floquet solutions, which has been already excluded by Aubry's duality. So the eigenvalues are both equal to either +1 or -1. To exclude coexisting solutions, B can only be reduced to an upper triangular matrix by change of basis, namely

$$B = \pm \begin{bmatrix} 1 & c \\ 0 & 1 \end{bmatrix}, \quad \text{with } c \neq 0.$$

The miracle

In his paper Puig (2004) reports the following: if φ is a Bloch wave solution of Eq. (20), then it can be chosen to be real valued and the following matrix

$$Z(x) = \begin{bmatrix} \varphi(x) & -\varphi(x-\alpha)/N(x) \\ \varphi(x-\alpha) & +\varphi(x)/N(x) \end{bmatrix}, \quad N(x) = \varphi(x)^2 + \varphi(x-\alpha)^2,$$

has determinant 1 and obey the following equation

$$S(x)Z(x) = Z(x+\alpha)B(x), \quad S(x) = \begin{bmatrix} E - 2\lambda\cos(x) & -1 \\ 1 & 0 \end{bmatrix}, \quad B(x) = \begin{bmatrix} 1 & b(x) \\ 0 & 1 \end{bmatrix}, \quad (23)$$

where $b(x)$ is a periodic function of x with same the same regularity as φ . Now, if there is a solution $g(x)$ of the following equation (called *cocycle equation*)

$$g(x + \alpha) - g(x) = b(x) - \bar{b}, \quad (\text{cocycle equation}) \quad (24)$$

then $B(x)$ is similar to the constant matrix B obtained by replacing $b(x)$ by $\bar{b}$. Integrating both sides over one period, such a solution exist only if $\bar{b} = \int_0^1 b(x)dx$. The term *similar* means that $B(x)G(x) = G(x+\alpha)B$ if $G(x)$ is defined as

$$G(x) = \begin{bmatrix} 1 & g(x) \\ 0 & 1 \end{bmatrix}$$

The main result at this point is Eliasson (1992, 1999) and Puig (2004).

Proposition 4. A Floquet–Bloch solution exists if and only if the transfer matrix $S(E, \lambda; x)$ is reducible as in Eq. (23). A gap at the energy E is open if and only if the matrix $B(x)$ is similar to a constant matrix distinct from the identity 1.

Solving the Ten Martini problem

To solve the Ten Martini Problem, Avila and Jitomirskaya distinguish two regimes. The first regime, called Liouville, deals with numbers with $\beta > \ln \lambda$ and the other regime, called Diophantine, looks at numbers with $\beta < \ln \lambda$. Actually there is a special treatment to be done for $\beta \leq \ln \lambda \leq 2\beta$. The treatment of this delicate regime will be skipped. This article is devoted to make the main ideas accessible to physicists.

The Diophantine regime

While the Diophantine Regime is most technical and requires fine analysis, it has been considered since the earliest work by [Dinaburg and Sinai \(1975\)](#) on the Almost Mathieu equation. The strategy they used was inspired by the method of the KAM Theorem, proposed first by Kolmogorov in 1952 and then by Arnold and Moser in 1962–1963 to treat perturbation theory in Classical Mechanics. The main difficulty comes from what astronomers of the 19th century called *secular terms* and called today the *small divisor problem*. Such a situation is already contained in the solution of the cocycle equation (see [Eq. 24](#)). Indeed, to solve this equation, let $g(x)$ be expanded in Fourier series

$$g(x) = \sum_{m=-\infty}^{m=+\infty} e^{2i\pi mx} \hat{g}_m, \quad b(x) = \sum_{m=-\infty}^{m=+\infty} e^{2i\pi mx} \hat{b}_m, \quad \hat{b}_0 = \int_0^1 b(x) dx = \bar{b}.$$

Thus

$$\hat{g}_m = \frac{\hat{b}_m}{e^{2i\pi m\alpha} - 1}, \quad \forall m \neq 0.$$

If α is irrational, the Fourier coefficients of g are all well defined apart from $\hat{g}_0$, which can be chosen arbitrarily. The problem comes from numbers m 's such that $m\alpha$ is very close to a rational number. For instance if $m = q_n$, one of the continued fraction rational approximations, then $|q_n\alpha - p_n| \leq 1/q_{n+1}$. Therefore, using the definition of β this gives

$$|e^{2i\pi q_n\alpha} - 1| \leq 2\pi e^{-\beta q_n},$$

which can be very small, leading the Fourier series for g to diverge. To solve this problem, the trick is to use functions $b(x)$ that can be analytically continued in the complex plane replacing x by $z = x + i\gamma$ with $|\gamma| < \delta$ for a suitable $\delta > 0$. Then this is possible provided $|\hat{b}_m| \leq \text{const.} e^{-\delta|m|}$ for all m . In this case as long as $\beta < \delta$, the cocycle equation can be solved with g analytic in $|\gamma| = |\text{Im } z| < \delta - \beta$.

Why is this relevant? Because, as guessed by [Aubry and André \(1980\)](#), the decay of the wave functions solution of the dual equation (21) is given by the *Lyapunov exponent* γ , namely, the behavior at infinity of the transfer matrix between the sites N and $N + n$ as $n \rightarrow \pm\infty$. A beautiful argument from [Herman \(1983\)](#) using the properties of subharmonic function leads to

$$\gamma = \begin{cases} 0 & \text{if } 0 \leq \lambda \leq 1 \\ \ln \lambda & \text{if } \lambda \geq 1 \end{cases}.$$

Consequently, as proved by Sinai (see [Puig, 2004](#))

Theorem 5. *If $0 < \lambda < 1$, the dual equation (21) admits a unique solution $\hat{\varphi}$ such that, for some $C > 0$*

$$\frac{\hat{\varphi}(l+1)^2 + \hat{\varphi}(l)^2}{\hat{\varphi}(1)^2 + \hat{\varphi}(0)^2} \leq C e^{-2|\ln \lambda||l|}, \quad |l| \rightarrow \infty.$$

Equivalently the Almost Mathieu equation (20) admits a unique Floquet–Bloch solution that can be extended by analyticity to $z = x + i\gamma$ in the complex plane, in the strip defined by $|\text{Im } z| < |\ln \lambda|$.

Corollary 1. *If $0 < \lambda < 1$, the cocycle equation (24) admits a solution if α satisfies $\beta(\alpha) < |\ln \lambda|$, analytic in the strip $|\text{Im } z| < |\ln \lambda| - \beta(\alpha)$. In particular, all spectral gaps of the Almost Mathieu operator, but at $E = 0$, are open.*

Proof. Indeed the function $b(x)$ obtained in [Eq. \(23\)](#) is a function computable in terms of the Floquet–Bloch solution φ and is analytic in the same strip as φ . From [Theorem 5](#), this domain is the strip $|\text{Im } z| < |\ln \lambda|$. From solving the cocycle equation, the function g is analytic in $|\text{Im } z| < |\ln \lambda| - \beta(\alpha)$. At last if $E \neq 0$ due to the uniqueness of the solution of the dual equation, the constant $\bar{b}$ cannot vanish, proving that all gaps, but $E = 0$ are open for such α s.

The Liouville regime

If $\beta(\alpha)$ is large enough though, a different strategy can be used, which was initiated in the seminal paper of [Choi et al. \(1990\)](#). Indeed, the Hölder continuity of the gap edges can be used to estimate the gap size near a rational approximation of α to prove that the gap stay open. The main difference brought by Avila and Jitomirskaya is the use of the improved Hölder estimate proved at about the same time by [Avron et al. \(1991\)](#). This improved estimate permits to extend the arguments to irrational numbers with $\beta(\alpha) > 2|\ln \lambda|$.

The argument (with many details skipped) goes as follows: let $g_x = (E_-(x), E_+(x))$ be a spectral gap for the Almost Mathieu operator. Thanks to Avron et al. (1991), there is a constant $C_H > 0$ such that $|E_\sigma(x) - E_\sigma(x')| \leq C_H \sqrt{|x - x'|}$ for $\sigma = \pm 1$. If p_n/q_n is a rational approximation of x obtained from the continued fraction expansion, it follows that $|x - p_n/q_n| \leq c_1 e^{-\beta q_n}$ if $\beta > \beta(x)$ and if n large enough while c_1 is some positive constant. Therefore

$$\left| E_\sigma(x) - E_\sigma\left(\frac{p_n}{q_n}\right) \right| \leq C_H \left| x - \frac{p_n}{q_n} \right|^{1/2} \leq c_1 e^{\beta q_n/2}.$$

It follows that for the gap width this leads to the following inequality

$$|E_-(x) - E_+(x)| \geq \left| E_-\left(\frac{p_n}{q_n}\right) - E_+\left(\frac{p_n}{q_n}\right) \right| - 2c_1 e^{\beta q_n/2}.$$

Thanks to Choi et al. (1990), the gap width for p_n/q_n is bounded from below by

$$\left| E_-\left(\frac{p_n}{q_n}\right) - E_+\left(\frac{p_n}{q_n}\right) \right| \geq c_0(\lambda)(c_1\lambda)^{q_n/2}, \quad 0 < c_1 < 1.$$

where $c_1 > 0$ is some numerical constant (see Eq. 17 valid for q_n odd, for instance). As $n \rightarrow \infty$, one can choose β sufficiently close to $\beta(x)$. From this it follows that if $\beta(x) > |\ln \lambda| + |\ln D|$, the gap g_x is open.

So, there might still be a gap in the range of values of $\beta(x)$ for which the sketch of the proof presented above might fail to show that the gaps stay open. The paper by Avila and Jitomirskaya fills the gap in between.

Conclusion

This article is aimed at explaining to an audience of nonexpert scientists the strategy required to solve the Ten Martini Problem. Nevertheless entering into some technical details is unavoidable. Many contributions were necessary, which spread over a quarter of a century to clarify each point until a synthesis of all the arguments could lead to the solution. Several contributions were appreciated as major steps, so much so as to be published by the highest rated Mathematical or Mathematical Physics journals.

Abstract

This chapter reports recent progresses on the observation of Hofstadter butterfly in graphene, and organized as follows. We first briefly introduce the concept of Hofstadter butterfly, including the theoretical model of Bloch electrons in the magnetic field, the resulting Harper's equation and its solution, and its realizations in non-graphene systems. Then, we discuss the ways to realize the fractal Hofstadter spectra in graphene, and introduce three types of graphene superlattice structure, including graphene/hBN, twisted graphene layers, nanofabricated graphene superlattice. In particular, details about the fractal Hofstadter spectrum in graphene will be focused and discussed in the graphene/hBN superlattice and the twisted bilayer graphene.

Key points

- Introduction of Hofstadter Butterfly and the realization in non-graphene systems
- Graphene superlattices: graphene/hBN, twisted graphene layers, nanofabricated graphene superlattice
- The realization of fractal Hofstadter butterfly in Graphene/hBN superlattice
- Topological Chern insulators and Hofstadter butterfly in Twisted bilayer graphene

Introduction

Hofstadter butterfly refers to the energy spectrum of two-dimensional (2D) electrons being subjected to both the periodic electrostatic potential and a perpendicular magnetic field (B), which leads to a self-similar recursive Landau level spectrum resembling a butterfly. It is named after D. Hofstadter who first obtained the fractal energy spectrum mathematically for a square lattice in 1976 (Hofstadter, 1976). He assumed that the tight-binding Bloch energy has the form of $2E_0(\cos k_x\lambda + \cos k_y\lambda)$, where E_0 is an empirical parameter, λ is the electrostatic potential period, and $\mathbf{k}$ is the wave vector. He then replaced the momentum by doing a Peierls substitution, i.e., $\hbar\mathbf{k} \rightarrow \hbar\mathbf{k} - e\mathbf{A}$, where e is the electron charge and $\mathbf{A}$ is the vector potential with $\mathbf{B} = \nabla \times \mathbf{A}$. By solving the time-independent Schrodinger equation with the ansatz of $\psi(x, y) = g_n e^{i\alpha m}$, where $x = n\lambda$ and $y = m\lambda$ (n and m the integers) with α depends on energy, one could obtain Harper's equation:

$$g_{n+1} + g_{n-1} + 2 \cos(2\pi n\phi/\phi_0 - \alpha)g_n = \varepsilon g_n,$$

with $\phi = B\lambda^2$ is the magnetic flux through the unit cell, $\phi_0 = h/e$ is the magnetic quantum flux with h the Planck constant, and $\varepsilon = 2E/E_0$ with E the energy. At rational fillings with $\phi/\phi_0 = p/q$, where p and q are co-prime integers, the solution of the Harper's equation reveals that the Bloch band would split into q distinct energy subbands, resulting in a recursive fractal energy diagram as shown Fig. 1, the so called Hofstadter butterfly.

In 1978, Wannier (1978) took the density of state into account and transformed the fractal energy spectrum into a linear trajectory of density-field diagram, so called Wannier diagram. In this representation, the Hofstadter butterfly is described by the Diophantine relation:

$$n/n_0 = t(\phi/\phi_0) + s$$

Here n is the carrier density and n_0 is the carrier density of a unit cell. The first quantum number t corresponds to the topological properties of Landau level flat band and the second quantum number s is the Bloch band filling index. Later on, the fractal spectrum was also calculated for triangular lattices (Claro and Wannier, 1979) and honeycomb lattices (Rammal, 1985).

To experimentally observe the Hofstadter butterfly is rather challenging. The minigaps of the fractal spectrum is considerable when magnetic flux is comparable to the quantum flux, in other words, the magnetic length $l_B = \sqrt{\hbar/eB}$ is of the same order as λ , the period of electrostatic potential of the Bloch band. For a real crystal, the period is the lattice constant, which is of the order of

sub-nanometer, and thus it usually requires an extremely large magnetic field over 1000T that is experimentally inaccessible in the lab. Back in the 1990s, electrostatic periods much larger than its lattice constant were achieved by fabricating lateral superlattices for 2D electron gas in GaAs/AlGaAs heterostructures (Schlösser et al., 1996; Albrecht et al., 1999, 2001, 2003; Geisler et al., 2004). Although signatures of Hofstadter spectrum were observed in these artificial superlattices, the device quality degradation due to nanofabrication as well as the difficulty in tuning carrier density hindered the revelation of the fractal structure.

The fractal Hofstadter spectrum was vividly realized in a microwave waveguide with a periodic arrangement of scatterers (Kuhl and Stöckmann, 1998). In this photonic system, the transmission matrix mimics the Hamiltonian of Bloch electrons in the magnetic field, and equivalently leads to the Harper equation and a fractal Hofstadter butterfly. Similar realizations of the Hofstadter Hamiltonian were also reported in optical lattices with ultracold atoms (Aidelsburger et al., 2013) and in superconducting qubits (Roushan et al., 2017).

Graphene superlattices

Being atomically thin, graphene is an ideal 2D electron system. Soon after the discovery of quantum Hall effect in graphene (Novoselov et al., 2005; Zhang et al., 2005), calculations of the fractal Hofstadter spectrum were carried out in monolayer graphene (Hasegawa and Kohmoto, 2006) and bilayer graphene (Nemec and Cuniberti, 2007). Yet, the problem is obvious as the graphene lattice constant is small, $a = 0.246$ nm, thus requiring a superlattice structure.

One solution is to realize graphene superlattice structures with external periodic potentials, whose band structure was calculated by Park et al. (2008), revealing an emergence of secondary Dirac point at the superlattice Brillouin zone boundary. Similar calculations were also done by Brey and Fertig, 2009, and Barbier et al., 2010. The first and also the best experimental demonstration is the moiré superlattice structure on graphene/hexagonal boron nitride (hBN) heterostructure, formed due to their lattice mismatch as illustrated in Fig. 2A. The graphene/hBN superlattice was initially observed in a scanning tunneling microscope/spectrum (STM/STS) study by Yankowitz et al. (2012). Perfect twist angle control with the $\theta = 0^\circ$ was realized via direct epitaxy of graphene on hBN with a superlattice period of ~ 15.6 nm (Yang et al., 2013). Note that the twist angle between graphene

Fig. 2 Sketches of graphene superlattice structures formed by lattice constant mismatch (A), nanofabrication (B), and twisting between graphene layers (C).

and hBN could also be tuned by thermal annealing (Wang et al., 2016) and AFM tip manipulation (Koren et al., 2016; Wang et al., 2016; Ribeiro-Palau et al., 2018). The fractal Hofstadter spectrum was realized in transferred graphene/hBN superlattices (Dean et al., 2013; Hunt et al., 2013; Ponomarenko et al., 2013; Yu et al., 2014; Wang et al., 2015; Krishna Kumar et al., 2017, 2018; Spanton et al., 2018), in epitaxial graphene/hBN superlattices (Yang et al., 2013, 2016; Chen et al., 2017; Lu et al., 2020), and in ABC-trilayer graphene/hBN superlattice (Chen et al., 2020a). Soon after the experimental observations, the fractal Hofstadter spectrum were calculated in graphene/hBN superlattice (Chen et al., 2014).

Besides, there are also other graphene superlattices based on nanofabrication, such as one-dimensional (1D) superlattices with a comb-like gate (Dubey et al., 2013; Drienovsky et al., 2014), etched graphene antidots (Sandner et al., 2015; Yagi et al., 2015), and patterned dielectric superlattice (Forsythe et al., 2018), as sketched in Fig. 2B. However, the results are not promising. The 1D gated superlattices suffered from serious p-n junction effects, and the graphene antidots were limited by its big superlattice size and thus dominated by classic commensurate effect between the superlattice period and the cyclotron orbits. The patterned dielectric superlattices with a reduced period of ~ 40 nm and a stronger tunability of the periodic potential revealed signatures of the fractal spectrum; however, the quality was still limited as it suffered from similar problems as those of lateral superlattices of the 2D electron gas in GaAs/AlGaAs heterostructures.

Another strategy in this effort is a moiré butterfly by rotating two graphene layers with the period of $\lambda = a/(2 \sin(\theta/2))$ at a twisted angle (θ) (Fig. 2C). This was firstly proposed in (Bistritzer and MacDonald, 2011b), where fractal spectrum at a strong field limit ($\phi/\phi_0 > 1$) was investigated. Later, calculations of the fractal spectrum at a weak field limit ($1 > \phi/\phi_0 > 0$) were carried out in twisted bilayer graphene (TBG) for different twist angles by Moon and Koshino (2012) and Wang et al. (2012). In fact, the moiré superlattice structure of the TBG were observed in a series of the STM experiments (Li et al., 2010; Luican et al., 2011; Brihuega et al., 2012). In the early works of quantum transport on TBG prepared either by CVD growth on SiC (Lee et al., 2011) or by folded graphene (Schmidt et al., 2014), the device quality was much limited and no signature of the fractal band was observed. Thanks to the development of “pick-up” transfer technique (Wang et al., 2013) and subsequent “tear and stack” technique using the same graphene flake (Kim et al., 2016a), accurate control of twist angle in TBG and high-quality devices were possible. In 2016, realizations of TBG with $\theta \sim 2^\circ$ (corresponding to $\lambda \sim 7$ nm) were reported by Kim et al. (2016b) and Cao et al. (2016), where two sets of LLs were observed; one stemming from the main charge neutral point (CNP) and the other from the superlattice gaps (or called full filling $n = 4n_0$). However, the two LLs intersect each other without revealing the recurring fractal structures. Then, the magic angle TBG with $\theta \sim 1.1^\circ$ (corresponding to $\lambda \sim 12.8$ nm) was firstly realized by Cao et al. (2018a,b), where the LLs are observed to fan out of the main CNP and superlattice gaps, and later by (Lu et al., 2019; Yankowitz et al., 2019) with the LLs developed from half filling and quarter fillings. The fractal Hofstadter spectrum was also observed in other twisted graphene multilayer moiré systems including but not limited to the twisted double bilayer graphene (TDBG) (Burg et al., 2019; Cao et al., 2020; Liu et al., 2020; Shen et al., 2020), twisted monolayer bilayer graphene (TMBG) (Chen et al., 2020b; Polshyn et al., 2020, 2021; He et al., 2021; Xu et al., 2021), and twisted trilayer graphene (TTG) (Hao et al., 2021; Park et al., 2021b; Siriviboon et al., 2021).

Hofstadter butterfly in graphene/hBN superlattice

In graphene/hBN heterostructure, graphene and hBN share a similar triangular lattice with a mismatch of $\delta = \sim 1.7\%$, which gives a triangular moiré superlattice with a period of $\lambda = (1 + \delta)a/\sqrt{2(1 + \delta)(1 - \cos\theta) + \delta^2}$ at a given twist angle (θ). The area of the superlattice unit cell $A = \sqrt{3}\lambda^2/2$ defines the number of electron states per area of a fully filled Bloch band $n_0 = 1/A$. Here, the carrier density n can be largely tuned by gating $n = C_G V_G/e$, where C_G (V_G) is the geometrical capacitance (gate voltage), and the magnetic flux is defined by $\phi = BA$. Then, the measured Landau fan diagram, a mapping of longitudinal resistance (R_{xx}) or Hall resistance (R_{xy}) to the change of V_G and B , could be transformed into the Wannier diagram of the fractal Hofstadter butterfly spectrum, as shown in Fig. 3, following the Diophantine relation: $n/n_0 = t(\phi/\phi_0) + s$, where both t and s are integers in the single-particle picture.

At zero magnetic field, i.e., $\phi/\phi_0 = 0$, the R_{xx} peak at $s = 0$ corresponds to the charge neutral point (CNP) of graphene, while two satellite peaks developed at $s = \pm 4$ are referred to the gap openings at the moiré mini-Brillouin zone boundary (or called secondary Dirac points in some literatures), and the number 4 also means the fourfold degeneracy (spin and valley) of the Bloch band, i.e., 4 electrons/holes to fully filled one moiré unit cell. There is electron-hole asymmetry, and usually the superlattice effect is stronger for holes than that for electrons.

At $s = 0$, the Diophantine relation is simplified to $n/n_0 = t(\phi/\phi_0)$. This is exactly the case of 2D free electrons/holes subjected to a perpendicular magnetic field, and the quantum number t has the same physical meaning as the filling factors of Landau levels in graphene where the Hall conductance is quantized to te^2/h . Let us take the monolayer (bilayer) graphene/hBN superlattice as an example. The states developed at $t = 4N + 2$ ($4N$ for bilayer graphene) means that the Landau quantization gaps with fourfold symmetry, while those at other integers are corresponding to the gaps with broken symmetry, with $N = 0, 1, 2, \dots$. Landau level index ($N = 1, 2, 3, \dots$ for bilayer graphene).

At $s = \pm 4$, the Diophantine relation can be modified as $(n/n_0 \mp 4) = t(\phi/\phi_0)$. At a small magnetic field before the Landau quantization, the sign of R_{xy} changes at $s = \pm 4$, which is exactly the same as sign change of R_{xy} at CNP. As the magnetic field increases further, features of the Landau level states are found fanning out from $s = \pm 4$ with a slop of $t = (\phi/\phi_0)/(n/n_0 \mp 4)$, similar

Fig. 3 Fractal Hofstadter butterfly revealed in a color mapping of conductance to magnetic field B and gate voltage V_g (A) and corresponding Wannier diagram (B) in graphene/hBN superlattice. Reproduced from Hunt B., Sanchez-Yamagishi J.D., Young A.F., Yankowitz M., LeRoy B.J., Watanabe K., Taniguchi T., Moon P., Koshino M., Jarillo-Herrero P., et al. (2013) Massive Dirac Fermions and Hofstadter butterfly in a van der Waals heterostructure. *Science* 340, 1427–1430.

to those fanning out from CNP with a slope of $t = (\phi/\phi_0)/(n/n_0)$. The whole spectra stemming at $s = \pm 4$ is like a replica of those at CNP, a signature of fractal Hofstadter butterfly. Note that the LLs stemmed from $s = -4$ show up at almost the same magnetic field as those at the CNP.

The most intriguing evidence of the fractal Hofstadter spectrum is revealed at the fractional filling $\phi/\phi_0 = p/q$. If $p = 1$ as in most cases, the LLs from $s = -4$ and those from $s = 0$ intersect at $\phi/\phi_0 = 1/q$. For instance, the LLs with $t = 2$ from $s = -4$ will meet those with $t = -2, -6$, and -10 from $s = 0$ at $q = 1, 2$, and 3 , respectively, as shown in Fig. 3B (Hunt et al., 2013). At these crossing points, mini Hofstadter gaps open at $\phi/\phi_0 = 1/q$, and moreover LLs with different t are developed at an effective magnetic field $B_{\text{eff}} = \pm |B - B_{1/q}|$, whose traces at $B = 0$ could be any integer s between 0 and -4 . In principle, similar recursive fractal gaps should be found at other crossing points in the Wannier diagram, and the whole spectrum constructs the fractal Hofstadter butterfly. Note that the fractional s with an integer t (also named symmetry broken Chern insulator) as well as a fractional t with $s = 0$ (fractional quantum Hall insulator) are observed in graphene/hBN superlattice (Wang et al., 2015). Moreover, gaps with both fractional s and fractional t (also named fractional Chern insulator) are revealed in bilayer graphene/hBN superlattices (Spanton et al., 2018), indicating fractional Hofstadter butterfly spectra in the many-body picture.

The fractal Hofstadter spectrum can be probed in conductance measurement (Dean et al., 2013; Hunt et al., 2013; Ponomarenko et al., 2013; Wang et al., 2015; Yang et al., 2016; Chen et al., 2017; Krishna Kumar et al., 2017) and also in capacitance measurements (Hunt et al., 2013; Yu et al., 2014; Spanton et al., 2018). Note that the fractal Hofstadter butterfly spectra can survive at elevated temperature up to 100 K (Krishna Kumar et al., 2017, 2018), even though the fractal Hofstadter butterfly spectra are thermally smeared into Brown-Zak oscillations, i.e., the conductance oscillations in ϕ_0/ϕ .

Hofstadter butterfly in twisted bilayer graphene

The situation in TBG are more complicated and interesting, because now the twisted angle (θ) determines not only the size of the moiré superlattice $\lambda = a/(2 \sin(\theta/2))$, but also the interlayer coupling. At a magic angle of $\sim 1.05^\circ$, the resulting moiré bands are extremely flat with a bandwidth of ~ 10 meV, implying a reduced Fermi velocity (Bistritzer and MacDonald, 2011a). The moiré flat band in the magic angle TBG gives rise to the strong electron correlation effects, including the correlated insulators at half fillings and superconductivity nearby (Cao et al., 2018a,b), as well as correlator insulators at quarter fillings (Lu et al., 2019; Yankowitz et al., 2019). In TBG, it is convenient to define the moiré band filling factor ($\nu = n/n_0$), corresponding to the number of carriers filled

in the moiré conduction/valence band, with $n_0 = 1/A$ and $A = \sqrt{3}\lambda^2/2$. As a result, the resistance peaks at $\nu = \pm 1$ (± 3), ± 2 , ± 4 in the transfer curve are corresponding to the correlated insulators at quarter (three quarters) fillings, half fillings, and moiré band insulators, respectively.

The fractal Hofstadter butterfly spectrum in TBG is also revealed in the Wannier diagram, following the Diophantine relation: $n/n_0 = t(\phi/\phi_0) + s$, where both t and s are integers in the single-particle picture. The strong electron-electron interactions in TBG could substantially reshape the fractal Hofstadter spectrum. Usually, the correlated insulators are quite robust against the magnetic field, and the replica of the LLs emerges at these integer fillings ν , unlike the dominating LLs at $\nu = 0$ and ± 4 in graphene/hBN superlattice. Note that the LL filling factor ν_{LL} in the replica spectrum at non-zero integer ν is usually twofold or even onefold degenerate, and the filling factors ν_{LL} have the same sign as those of ν . In addition, the quantum oscillations in TBG are usually much weaker than those in the graphene/hBN superlattice. This is due to the reduced Fermi velocity of the flat band, especially for MATBG, and therefore the Landau quantization gaps as well as the fractal Hofstadter gaps are smaller compared to the dispersive moiré bands in the graphene/hBN superlattice.

Additionally, these moiré flat bands in TBG are topological with non-trivial Berry curvatures (Liu et al., 2019a,b) at zero magnetic fields. The zero-field topological bands are mathematically the same as those LLs or fractal LLs at finite magnetic fields. Note that the quantum Hall insulator is in principle a Chern insulator where the LL filling factor corresponds to the Chern number, and here we use “Chern” specifically for the moiré Chern bands to avoid confusion. Considering spin, valley, and the moiré valley, the moiré bands are eightfold degenerate at the Dirac point, protected by the C_2T symmetry where C_2 is the inversion symmetry and T is time reversal symmetry.

If C_2T symmetry is unbroken, then the total Chern number is zero since the moiré bands with opposite Chern numbers touches at the Dirac point, even though each of the moiré bands are topological with $C = \pm 1$. This can be related to the fragile topology (Ahn et al., 2019; Po et al., 2019; Song et al., 2019; Lian et al., 2020), whose signature is revealed in the observation of the $C = 0$ band gaps being intersected by the non-zero LLs at $\phi/\phi_0 = 2$ ($B \sim 9T$) in the TBG with $\theta \sim 0.45^\circ$ (Lu et al., 2021).

If the inversion symmetry is broken by a staggered potential mass while the T symmetry is preserved, it leads to $C = +1$ at the K valley and $C = -1$ at the K' valley in the moiré conduction band, and $C = -1$ at the K valley and $C = +1$ at the K' valley in the moiré valence band. As a result, the Chern insulator with $C = +1$ or -1 emerge when the odd number of carriers is filled in the moiré band. The breaking of the C_2 symmetry happens when the TBG is aligned with the hBN lattice, first realized by A. Sharpe (Sharpe et al., 2019) with the observations of ferromagnetism and Chern insulator with $C = 1$ at $\nu = 3$, and then by Serlin et al. (2020) with the observation of quantized anomalous Hall effect (QAH) with $C = 1$ at $\nu = 3$, as shown Fig. 4A. Similar observations have also been observed in ABC-trilayer graphene/hBN superlattice (Chen et al., 2020a), twisted monolayer bilayer graphene (Chen et al., 2020b; Polshyn et al., 2020). These observations are in stark contrast to the conventional fractal Hofstadter butterfly that strongly depends on the magnetic flux in the moiré superlattice.

If the T symmetry is broken by the electron-electron interaction induced Haldane mass (Haldane, 1988), it leads to $C = +1$ at both the K and K' valley in the moiré conduction band, and $C = -1$ at the K and K' valley in the moiré valence band. As a result, it gives a Chern insulator with Chern number depending on a sequential filling of carriers, i.e., $C = -4 - \nu$ for holes and $C = 4 - \nu$ for electrons (as shown Fig. 4B). The Chern insulators with the T symmetry-broken are observed in various experiments, for instance in

Fig. 4 (A) Observation of quantized anomalous Hall effect in hBN aligned TBG, i.e., $R_{xy} = h/(Ce^2)$ and $R_{xx} = 0$ h/e^2 with Chern number $C = 1$. (B) Observation of sequential filled Chern insulator with $C = 4 - \nu$. Panel (a): Reproduced from Serlin, M., Tschirhart C.L., Polshyn H., Zhang Y., Zhu J., Watanabe K., Taniguchi T., Balents L., Young A.F. (2020) Intrinsic quantized anomalous Hall effect in a moiré heterostructure. *Science* 367, 900–903. Panel (b): Reproduced from Das I., Lu X., Herzog-Arbeitman J., Song Z.-D., Watanabe K., Taniguchi T., Bernevig B.A., Efetov D.K. (2021) Symmetry-broken Chern insulators and Rashba-like Landau-level crossings in magic-angle bilayer graphene. *Nature Physics* 17, 710–714.

transport measurements (Das et al., 2021; Park et al., 2021a; Saito et al., 2021; Shen et al., 2021; Wu et al., 2021b) and scanning spectroscopic measurements (Nuckolls et al., 2020; Choi et al., 2021; Pierce et al., 2021). These Chern insulators are found to compete with the zero-field ground states in MATBG (Stepanov et al., 2021). These Chern insulators are also observed for the non-magic angle TBG fractal Hofstadter spectra at finite magnetic fields (Choi et al., 2021; Shen et al., 2021).

Moreover, fractional Chern insulators with fractional C and ν (referred to the fractional t and fractional s in the Diophantine language), symmetry-broken Chern insulators (non-zero integers t and fractional s), and charge density waves ($t = 0$ and fractional s) are observed in local compressibility measurements (Xie et al., 2021), and are also studied in the numerical calculations (Andrews and Soluyanov, 2020; Wang and Santos, 2020). Similar topological phases with a fractional ν are also observed in the twisted monolayer-bilayer graphene (Polshyn et al., 2021) and twisted trilayer graphene (Siriviboon et al., 2021).

All these Chern insulators as well as CDW phases are weakly dependent on the filling of the magnetic flux, unlike the fractal and fractional fractal Hofstadter spectra in graphene/hBN superlattices. In fact, it is also possible to suppress the Chern insulators and recover the conventional fractal Hofstadter spectrum by twisting away from the magic angle (Shen et al., 2021). Because the moiré bands are more dispersive for the non-magic angle, which leads to stronger Landau quantization (bigger fractal Hofstadter gaps) and weaker electron interactions (smaller Chern gaps). Also note that the moiré bands in TBG at a non-magical angle might be topologically trivial. Besides, it is also possible to reveal the fractal Hofstadter spectra in the MATBG by tuning the Fermi level from the flat moiré bands to the dispersive remote bands (Das et al., 2021). Last but not least, aside from TBG, other twisted graphene multilayer system offers a good opportunity to study the electrical field tunable Hofstadter spectrum. Take the TDBG for example, the Landau fan diagram of the Hofstadter butterfly spectrum is strongly displacement field tunable (Liu et al., 2022a) and stacking order dependent (Crosse et al., 2020; Wu et al., 2021a), and the valley polarized correlated insulators at half fillings in TDBG are observed topological (Liu et al., 2022b) and could host insulating quantum oscillations (Liu et al., 2022a). These observations suggest a rich interplay among the moiré flat band topology, symmetry, Landau quantization and others.

Conclusion

Graphene is an ideal platform to experimentally realize the fractal Hofstadter butterfly. The development of van der Waals stacking techniques allows the realizations of high-quality graphene superlattice structures, including the graphene/hBN superlattice and the TBG and other twisted graphene multilayers. In a graphene/hBN superlattice, the recursive nature of the fractal Hofstadter spectra has been vividly revealed at rational fillings of ϕ/ϕ_0 . In TBG, the fractal Hofstadter spectra is strongly twist-angle dependent. In particular, the magic angle TBG reveals abundant topological Chern insulators including the quantized anomalous Hall effect at zero magnetic field, which is distinct from the conventional fractal Hofstadter spectrum.

Abstract

The Slater-Koster (SK) method was originally developed as a technique for interpolating first-principles energy bands from a limited number of k-points to a large one, for the purpose of accurately determining Fermi surfaces and densities of states. Numerous applications of the SK method have been made and extensions to include total energy determinations. One extension of the SK approach is the Naval Research Laboratory Tight-Binding (NRL-TB) method which has been very successful in fitting a set of first-principles electronic structure results and in addition being capable to predict properties that were not fitted and to also perform molecular dynamics simulations. This review presents a summary of applications using the NRL-TB scheme which covers most of the elements in the periodic Table and examples for multi-component systems.

Key points

- The NRL tight-binding method uses the Slater-Koster method to reproduce first-principles results.
- The resulting parameters can predict results not included in the database.
- The reduced size of the Hamiltonian allows rapid evaluation of systems containing hundreds of atoms.
- Phonon spectra as well as defect, stacking fault, and surface energies can be computed.
- Finite-temperature molecular dynamics simulations can compute thermodynamic properties.
- One- and two-dimensional systems, as well as nanoparticles, can be modeled.

Introduction

In the linear combination of atomic orbitals (LCAO) method, the one-electron wave function is expressed as a linear combination of Bloch sums. When such an expansion is made to the wave function in the Schrödinger equation, one obtains a set of simultaneous linear equations that has a nonzero solution if the determinant of the coefficients vanishes, that is,

$$\tilde{H} - \varepsilon \tilde{S} = 0 \quad (1)$$

[☆]*Change History:* September 2022. DA Papaconstantopoulos and MJ Mehl updated all sections with minor changes. New figures have been added and changes made in tables.

The matrix elements in this equation have the form

$$H_{nm} = \sum_{R_j} \exp [ik \cdot (R_j - R_i)] \times \int \phi_n^*(\mathbf{r} - \mathbf{R}_i) \tilde{H} \phi_m(\mathbf{r} - \mathbf{R}_j) d^3r \quad (2)$$

and

$$S_{nm} = \sum_{R_j} \exp [ik \cdot (R_j - R_i)] \times \int \phi_n^*(\mathbf{r} - \mathbf{R}_i) \phi_m(\mathbf{r} - \mathbf{R}_j) d^3r \quad (3)$$

where R_i and R_j denote the positions of atoms located on orbitals ϕ_n and ϕ_m , respectively. The integrals in the above equations can, in principle, be calculated directly, however the most common practice has been to follow Slater and Koster (SK) (Slater and Koster, 1954). They suggested replacing these integrals by adjustable parameters that could be estimated from experiment, but which are generally determined by fitting to more elaborate electronic structure calculations. The size of the matrices $\sim H$ and $\sim S$ is determined by the number of atoms in the unit cell and the number of atomic orbitals on each site. So, for face-centered cubic (f.c.c.), body-centered cubic (b.c.c.), and simple cubic (s.c.) lattices with one atom per unit cell, $\sim H$ and $\sim S$ are 9×9 matrices representing one *s*-function, three *p*-functions, and five *d*-functions. The *f*-states have been omitted in most works, although there have been papers that provide extensions of the SK scheme that include *f*-orbitals (Durgavich et al., 2016). For diatomic lattices, such as hexagonal close-packed (h.c.p.) and diamond and in binary compounds the *spd* model will result in an 18×18 matrix. Often in semiconductors such as Si and Ge the *d*-states are not included and hence the size of the Hamiltonian is 8×8 . The full SK Hamiltonian for a monatomic material could require the determination of 81 parameters between each pair of atoms; however, SK showed that these parameters are related by symmetry operations that considerably reduce their actual number. The resulting independent matrix elements may be found in the tables given by SK. The reader is cautioned that some obvious typographical errors appear in these tables which have been corrected by users. Since the above summations are over the interatomic distances R_j , the number of parameters increases for calculations that include more than first nearest neighbors. In practice, no more than the third nearest neighbors are included. The integrals in [2] are three-centered since they are the product of an atomic wave function $\phi^*(\mathbf{r} - \mathbf{R}_i)$ centered on the atom at position R_i , an atomic wave function $\phi(\mathbf{r} - \mathbf{R}_j)$ located on the atom at position R_j , and a potential function inside the Hamiltonian H , centered on a third atom. These three-center integrals can be reduced to two-center integrals by approximating the potential energy as a sum of spherical potentials located on the same two atoms where the atomic orbitals are located. For the relationships between three- and two-center integrals, see Papaconstantopoulos (2015). Although working in three-center formalism has the advantage of fitting band structures more accurately, the two-center approximation has the distinct advantage that its parameters are transferable from one structure to another. This property of the two-center scheme makes it suitable to introduce bond-length dependence in the parameters which leads one to implementing a total energy capability in the SK method.

Since the 1960s there have been numerous applications of tight-binding (TB) theories, in particular the SK approach, to calculate electronic energy bands, densities of states, and, more recently, total energies, forces, and molecular dynamics simulations (Cleri and Rosato, 1993; Cohen et al., 1994; Gross et al., 1999; Groß et al., 2003; Haftel et al., 2004; Harrison, 1989; Mehl et al., 2000; Mehl and Papaconstantopoulos, 2002; Papaconstantopoulos and Mehl, 2003; Silayi et al., 2018; Shi and Papaconstantopoulos, 2004; Yang et al., 1998). There are two main uses of the TB theory. One is to determine a small number of parameters with the aim of providing a physical insight into the electronic structure without the necessity of going beyond a qualitative description. A classic example of this approach is the universal TB parameters of Harrison (1989). Harrison's TB theory has been of great educational value for a whole generation of scientists. More recently, extensions to this theory have been provided that greatly improve its accuracy. The other approach is to place emphasis on accurately reproducing the results of first-principles calculations by applying a least-squares procedure using a large number of parameters. The authors of this article have generally followed the second approach. A handbook by Papaconstantopoulos (2015) provides TB parameters for all elements in the periodic table, except for those with *f*-states. The handbook provides TB parameters in both two-center and three-center bases as well as in orthogonal and nonorthogonal representations, however these parameters are fitted to the ground state of each element and have very limited transferability to other volumes and structures. In addition, these TB Hamiltonians are not designed to compute total energies. The NRL-TB scheme (Cohen et al., 1994; Mehl and Papaconstantopoulos, 1996), on the other hand, which is discussed in the next section, is a two-center nonorthogonal TB method that uses environment-dependent parameters that capture the volume dependence of both the energy bands and the total energy.

To complete this introduction, the attention of the reader is drawn to a simple level of the TB theory, known as the second moment approximation (SMA), which originates from the Friedel model of rectangular density of states for the *d*-bands. The SMA method does not account for the band structure but, at least for the f.c.c. metals, reproduces well the total energy which has led to its wide use in molecular dynamics simulations. This method contains four adjustable parameters fitted to reproduce either experimental quantities or the total energies from first-principles calculations.

NRL tight-binding method

In the (Naval Research Laboratory) NRL-TB scheme, the on-site terms h_{il} are written as a polynomial

$$h_{il} = a_l + b_l \rho_i^{2/3} + c_l \rho_i^{4/3} + d_l \rho_i^2, \quad (4)$$

where i labels the atom and l the angular momentum of s , p , and d characters in the present form of the method.

The quantity ρ_i that appears in [4] is an embedded-atom-like “density” per atom given by the expression

$$\rho_i = \sum \exp(-\lambda^2 R_{ij}) F(R_{ij}), \quad (5)$$

where R_{ij} denotes the position of neighboring atoms from a central atom i , and $F(R_{ij})$ is the cutoff function. The quantities a_l , b_l , c_l , d_l , and λ are 13 parameters to be determined by a least-squares fit to the first-principles results. It is possible, within this scheme, for example, to split the d -onsite parameters to t_{2g} and e_g , or going even further, to have different parameters for the three p -orbitals and the five d -orbitals. It is also to be noted that this scheme has the flexibility of adding more terms in [4] to describe the density contributions from atom A to atom B (and vice versa) in the case of a binary material.

It was shown by SK that the two-center (spd) hopping integrals can be constructed from ten independent parameters $H_{ll'm'}$, where

$$(ll'm) = ss\sigma, sp\sigma, pp\sigma, pp\pi, sd\sigma, \\ pd\sigma, pd\pi, dd\sigma, dd\pi, \text{ and } dd\delta.$$

One notes that in the case of a binary material AB, there will be a set of four additional parameters

$$(ll'm) = ps\sigma, ds\sigma, dp\sigma, \text{ and } dp\pi.$$

In the NRL-TB, each of these parameters is expressed in the form of a second-order polynomial-times an exponential function

$$H_{ll'm}(r) = (e_{ll'm} + f_{ll'm}r + g_{ll'm}r^2) \\ \times \exp(-t_{ll'm}^2 r) F(r), \quad (6)$$

where r is the distance between atoms, $F(r)$ the cutoff function as in [5], and $e_{ll'm}$, $f_{ll'm}$, $g_{ll'm}$, and $t_{ll'm}$ are an additional set of 40 parameters (or 56 for the, A-B interactions) to be determined by fitting to the first-principles results. Since one usually fits to a nonorthogonal Hamiltonian, an additional set of 40 parameters is used (56 for A-B) for the overlap matrix following [6]. In cases where the validity of the parameters for interatomic distances much smaller than those in the original databases needs to be extended, one finds that the following form of overlap parameters is more successful

$$S_{ll'm}(r) = (\delta_{ll'} + p_{ll'm}r + q_{ll'm}r^2 + r_{ll'm}r^3) \\ \times \exp(-s_{ll'm}^2 r) F(r), \quad (7)$$

where $p_{ll'm}$, $q_{ll'm}$, $r_{ll'm}$, and $S_{ll'm}$ are the corresponding parameters of the overlap matrix and $\delta_{ll'}$ is the Kronecker delta.

In most TB approaches (Cleri and Rosato, 1993; Harrison, 1989), as well as in all the so-called “glue” potential atomistic methods (Finnis and Sinclair, 1984), one writes the total energy as a sum of a band energy term (sum of eigenvalues) and a repulsive potential $G[n(r)]$ that can be viewed as replacing all the charge density-dependent terms appearing in the total energy expression of the density-functional theory. The NRL-TB method has the unique feature that eliminates G by the following ansatz: a quantity V_0 is defined as

$$V_0 = G[n(r)]/N_e, \quad (8)$$

where N_e is the number of valence electrons and $n(r)$ is the charge density. All the first-principles eigenvalues $\varepsilon_i(\mathbf{k})$ are then shifted by the constant V_0 , and the shifted eigenvalue is defined as

$$\varepsilon'_i(\mathbf{k}) = \varepsilon_i(\mathbf{k}) + V_0 \quad (9)$$

The result of this manipulation is that the first-principles total energy E is given by the expression

$$E = \sum \varepsilon'_i(\mathbf{k}) \quad (10)$$

where the sum is over all occupied bands and all k -points in the Brillouin zone. It is noted that the constant V_0 is different for each volume and structure of the first-principles database. The reader should recognize that each band structure has been shifted by a constant, retaining the exact shape of the first-principles bands. It should also be stressed that all this is done to the first-principles database before one proceeds with the fit that will generate the TB Hamiltonian. The next step is to use a least-squares procedure to fit this database with the shifted eigenvalues ε_i to the TB Hamiltonian.

A typical database in the NRL-TB method contains, for example, in a transition metal, five volumes each for the f.c.c. and b.c.c. structures and often the s.c. lattice to achieve better transferability to other periodic structures or defect structures.

The TB method can also be extended to cover magnetism. In this case, a set of spin-polarized parameters are constructed by fitting to spin-polarized linearized augmented plane wave (LAPW) calculations. Common hopping [6] and overlap [7] parameters

are used for the majority and minority spin cases, but separate onsite [4] parameters for each channel are developed. Each channel is then diagonalized separately. A set of paramagnetic TB parameters is constructed by averaging the majority and minority spin onsite parameters. Next the pressure-induced ferromagnetic-to-paramagnetic transitions are studied by noting whether the spin-polarized or paramagnetic parameters produce lower energies. Currently well-tested parameters for Fe, Co, and Ni are available (Bacalis et al., 2001; Mehl and Papaconstantopoulos, 2005).

The parameters are fit to reproduce the first-principles total energies and eigenvalues by using the Levenberg-Marquardt algorithm to minimize the mean square error of the expression (McGrady and Papaconstantopoulos, 2021)

$$M = \sum_i w_E(i) |E_{LAPW}(i) - E_{TB}(i)|^2 + \sum_{i,j,n} w_B(i, k, n) |\epsilon_{LAPW}(i, k, n) - \epsilon_{TB}(i, k, n)|^2 \quad (11)$$

In Eq. 11, w_E is the weighting factor for the total energy for structure i , w_B the weight for the bands, E_{LAPW} and E_{TB} are the respective first-principles and TB total energies for the i^{th} structure and ϵ_{LAPW} and ϵ_{TB} are the eigenvalues for the n^{th} band and the k^{th} k-point of the i^{th} structure.

Technical procedure

The first-principles calculations were done either with the muffin-tin potential augmented plane wave (APW) method or with the full-potential LAPW method. The small differences between these two approaches, especially for closed packed structures, are within the error one makes after fitting to the TB Hamiltonian.

For the f.c.c., b.c.c., and s.c. structures uniform k -point meshes that include the origin and contain 89, 55, and $35k$ -points in the irreducible part of the Brillouin zone, respectively, are used. In most cases, the Hedin-Lundqvist parametrization of the local density approximation (LDA) to the density-functional theory (DFT) is used. In some cases, such as for spin-polarized iron (Bacalis et al., 2001), the generalized gradient approximation (GGA) has been used. Spin-polarized calculations were performed for the appropriate metals in the 3d transition series. For a typical transition metal, there are ~ 4000 eigenvalues and energies in the database. An IMSL package is used, based on a finite-difference Levenberg-Marquardt algorithm, to adjust the 93 parameters involved to reproduce this database by means of a nonlinear least-squares fit, with the total energies typically weighted ~ 200 times larger than the eigenvalues in a single band. Starting parameters are selected guided by those found in the previous work and it is ensured that the symmetry of the eigenstates is taken into account. This is an important issue because a block-diagonalization of the Hamiltonian avoids the possibility of incorrectly aligning the bands and preserves the angular momentum character of the states. For details of this symmetrization procedure, refer to (Mehl and Papaconstantopoulos, 1996).

Another issue is the number of bands per k -point used in the fit. Both occupied and empty states are fitted. For example, in the transition metals, the lowest six bands for all k -points are fitted but the bands 7–9 are also included for the four high-symmetry points. With this choice, one obtains reliable values for the SK parameters that correspond to the p -orbitals. The fitting RMS errors are in the range 1–5 mRy for six bands and ~ 0.5 mRy for the total energies. For the semiconductors, eight bands, divided into four valence and four conduction bands in an s - p basis are fitted. Here, the RMS error is ~ 5 mRy for the valence bands but much higher for the conduction bands. There is a very significant improvement in the conduction bands upon inclusion of the d -orbitals. However, the s - p basis gives a very good fit to the total energy with an RMS error not exceeding 0.5 mRy.

Fig. 1 shows an example of the accuracy of the TB fit: we show a comparison between the TB and LAPW energy bands for hcp beryllium (McGrady and Papaconstantopoulos, 2021). Clearly the TB Hamiltonian accurately reproduces the first-principles results.

Ground-state behavior and phase stability

The NRL-TB Hamiltonians have been tested to give the correct ground state for all materials for which TB parameters have been generated. The results are summarized in Tables 1 and 2. Table 1 shows the equilibrium lattice constants and bulk moduli for all the materials studied, comparing them to first-principles LDA calculations and to experiment. The equilibrium lattice constant is typically within 1–2% of the LDA value and correspondingly very close to the measured values. In this table, the magnetic elements are spin-polarized in a manner consistent with the observed magnetic structure. Thus, one can find that the ground state of chromium is an anti-ferromagnetic CsCl phase, which is a good approximation to the experimentally observed spin density wave.

Similarly, the equilibrium bulk moduli are in good agreement with the first-principles results, within 10% for most elements. Except for Ti, the h.c.p. phases were not fit to first-principles results, but instead predicted as an output of the TB scheme. As a result, the equations of state predicted by the TB model are not as accurate as for the cubic lattices. The largest error is for zirconium, where a is 7% smaller than experiment and c is 8% larger. Yttrium and hafnium also show large discrepancies between the TB model and experiment. The lattice constants for the other elements are within 2% of experiment, consistent with the errors one would find in first-principles calculations. The discrepancies from experiment found in Zr, Y, and Hf can be removed by including h.c.p. and, if necessary, the simple cubic lattice.

For Ti, the GGA calculations were fitted with the h.c.p. and s.c. lattices (Mehl and Papaconstantopoulos, 2005). In this more elaborate fit, it was possible to improve on the lattice constants and differentiate between the h.c.p. and ω phases. This TB method

Fig. 1 Comparison of the bands from the NRL-TB and LAPW methods for the HCP Be structure with $c/a = 1.6$ and a volume of 106 Bohr^3 (McGrady and Papaconstantopoulos, 2021). The LAPW bands are shown with a dashed line and the NRL-TB results are shown with a solid line. The Fermi energy is at 0 Ry.

Table 1 Equilibrium lattice constants and bulk moduli for the experimentally observed ground-state structures of the elements, comparing the results of the TB parametrization (Bernstein et al., 2000, 2002; Gotsis et al., 2002; McGrady et al., 2014; McGrady and Papaconstantopoulos, 2021; Mehl and Papaconstantopoulos, 1996; Wang et al., 2003; Yang et al., 1998), first-principles DFT, where available, and experiment

The energy of the experimental ground-state structure is arbitrarily set to zero. Energies for boron are relative to the R105 ground state (McGrady et al., 2014). All energies are calculated at the equilibrium volume found by the TB fit and are expressed in mRy. Below the common name of each phase is its *Strukturbericht* designation. The fit was made using LDA first-principles results except for those rows marked with an asterisk, which were fit to GGA results (Mehl and Papaconstantopoulos, 1996; Bernstein et al., 2000, 2002; Gotsis et al., 2002; McGrady et al., 2014; McGrady and Papaconstantopoulos, 2021; Sha et al., 2011; Durgavich et al., 2016)

succeeds in predicting the correct ground state for all materials presented here. Fig. 2 shows the energy volume curves for a representative sample of materials that crystallize in different structures. The results for all the elements are summarized in Table 2, which shows the equilibrium energy of each of these phases expressed as the difference in energy between that phase and the equilibrium energy of the experimental ground state. The energy of each crystal structure is computed by doing a conjugate-gradient minimization of the total energy with respect to all the parameters in the lattice, internal (atomic positions) as well as external (a , c , etc.). The TB method correctly predicts the ground-state structure for all metals including the ferromagnetic metals iron, cobalt, and nickel. The results are also consistent with the accepted crystal structure for the semiconductors Si and Ge, and with the more complex structures of Mn, Ga, and In.

As a further example, Fig. 3 shows the energy/volume behavior of boron (McGrady et al., 2014) in a variety of structures. The low energy states of boron are all consist of differing arrangements of regular icosahedra, a structure not seen in other elements. Tight-binding parameters were fit to DFT results for the f.c.c., b.c.c., s.c., and dhcp and boron R12 structure, the simplest of the boron structures. These parameters correctly predict the R105 structure to be lower in energy than the other known boron structures, however the R105 + vacancy structure is found to be the ground state. There is some uncertainty in the R105 structure, with some models only partially filling some sites. The prediction of a vacancy structure may be a reflection of these models.

The fact that this method finds the correct ground states of the h.c.p. metals and the other complex structures that were not included in the fit of the TB parameters should be emphasized.

The robustness of the TB parameters has also been established by studying crystal structures of lower symmetry such as the volume-conserving tetragonal strain, the so-called Bain path. The Bain path of Mo at the experimentally observed equilibrium volume of the b.c.c. phase is shown in Fig. 4 (Mehl and Papaconstantopoulos, 1996). The energy is properly a minimum for the b.c.c. lattice, where $c/a = 1$, and attains a local maximum at the f.c.c. structure ($c/a = \sqrt{2}$). This shows that the f.c.c. elastic constant associated with tetragonal shear, $C_{11} - C_{12}$, is negative; hence, the f.c.c. structure is unstable.

Elastic constants

Elastic constants measure the proportionality between strain and stress in a crystal, provided that the strain is not so large as to violate Hook's law. Computationally, the elastic constant is determined by applying a strain to a crystal, measuring the energy versus strain, and determining the elastic constant from the curvature of this function at zero strain (Mehl et al., 1994). A given strain is associated with a certain linear combination of elastic constants. For cubic systems, including diamond, there are three independent elastic constants, C_{11} , C_{12} , and C_{44} . One linear combination of the elastic constants is obtained from the bulk modulus

$$B(V) = VE''(V) = 1/3(C_{11} + 2C_{12}) \quad (11)$$

Fig. 2 Energy vs. volume curves for various phases of (clockwise from the top left) copper, vanadium, germanium, and titanium, using the NRL-TB parameters described in the text. Note that the method correctly predicts the equilibrium structure (Bernstein et al., 2002; Mehl and Papaconstantopoulos, 1996, 2002).

Fig. 3 Energy per atom versus volume per atom for possible structures of boron using the NRL tight-binding fit (McGrady et al., 2014). The R105_{hexvac} structure is the minimum energy of the R105 structure with one vacancy. The R12 structure was included in the tight-binding fit along with the standard structures. The energies of the remaining boron structures (R105, R105_{hexvac}, T190, T50, γ-28) are predicted from this fit.

where V is the unit cell volume. A second combination is most easily obtained by straining the crystal in the $(1\ 0\ 0)$ direction while simultaneously compressing it in the $(0\ 1\ 0)$ direction to conserve the volume, with lengths in the $(0\ 0\ 1)$ direction remaining fixed. If x is the fractional change in the $(1\ 0\ 0)$ direction, then,

$$E(x) = E_0 + V(C_{11} - C_{12})x^2 + O(x^4) \quad (12)$$

where the function, $E(x)$ measures the energy as a function of strain. Finally, one finds C_{44} by straining the crystal in the $(1\ 1\ 0)$ direction and fixing the volume by compressing in the $(1\bar{1}0)$ direction. In this case,

Fig. 4 TB calculation of the energy of molybdenum, at the experimental equilibrium volume, under a tetragonal strain, as a function of c/a . The vertical lines denote the positions of the b.c.c. and f.c.c. lattices (Mehl and Papaconstantopoulos, 1996).

$$E(x) = E_0 + \frac{1}{2} V C_{44} x^2 + O(x^4) \quad (13)$$

Note that for diamond the calculation of C_{44} requires the minimization of the total energy with respect to an internal parameter at each strain.

The calculation of elastic constants assesses the ability of the method to determine properties not included in the fitting database. The elastic constants of the cubic materials calculated by the NRL-TB approach are compared to the experimental values in Table 3. These calculations were performed at the experimental volume and therefore they are not consistent with the equilibrium value of B found in Table 1. The deviation of the calculated C_{11} and C_{12} from the measured values is within 10–15% which is very close to the error one finds when comparing with a direct evaluation from first-principles calculations.

An inspection of Table 3 reveals somewhat larger errors for C_{44} . A solution to this problem is to fit C_{44} either to LAPW calculations or to experiment. It should be noted here that calculations of C_{ij} in the alkaline-earth metals is problematic because the lattice is extremely soft. One can also note that the method correctly reproduces the sign of the elastic constant difference $C_{12} - C_{44}$, even in the metals rhodium and iridium, and the semiconductors Si and Ge where it is negative. It is worth mentioning that this negative sign cannot be obtained from the standard embedded-atom method, and that a model with only central forces would have $C_{12} = C_{44}$, the Cauchy relationship.

The elastic constants for the h.c.p. structure are C_{11} , C_{12} , C_{13} , C_{33} , and C_{44} (Mehl et al., 1994). The elastic constants found by the NRL-TB method show larger relative deviations from experiment than found in the cubic crystals. These were found from TB parameters fitted only to cubic lattices. It is shown, in the case of Ti, that if one extends the fitting database to include the h.c.p. lattice as well, there is a dramatic improvement in the comparison of TB and measured elastic constants.

Vacancies

Vacancy formation energies have been calculated by a supercell method. One atom in the supercell is removed and neighboring atoms are allowed to relax around this vacancy while preserving the symmetry of the lattice. The great advantage of the NRL-TB method over first-principles approaches is that one can do the calculation in a very large supercell, in a computationally efficient manner, including relaxation. It is found that a supercell containing 128 atoms is sufficient to eliminate the vacancy-vacancy interaction. The vacancy formation energy is given by

$$E_{\text{vac}}(N) = E(N-1) - (N-1) E(N, 0)/N \quad (14)$$

where $E(M, Q)$ is the total energy of a supercell containing $M + Q$ sites, where M are occupied by atoms and Q are vacant, whence $E(N, 0)$ is N times the energy of one atom in its bulk crystal structure. The experimental lattice constant is used to set the volume of the system, since under experimental conditions the lattice constant of a metal containing isolated vacancies will be the lattice constant of the bulk metal.

Calculated values of the vacancy formation energy of the metals (Mehl and Papaconstantopoulos, 1996) (in eV) are shown in Table 4. (Note that vacancy formation energies for Si and Ge are shown in Table 6). Relaxation around the vacancy was included via a conjugate gradient procedure but it introduced, not unexpectedly, a small effect. Where available, it is compared to both first-principles calculations and experiment (Schaefer, 1987). The results for niobium, silver, tantalum, and iridium are in excellent agreement with experiment. The vacancy formation energies for rhodium, tungsten, and platinum do not compare well with

Table 3 Elastic constants for cubic elements (in GPa).

All calculations were fit to LDA first-principles results except for those rows marked with an asterisk, which were fit to GGA calculations (Bernstein et al., 2000, 2002; McGrady et al., 2014; McGrady and Papaconstantopoulos, 2021; Mehl and Papaconstantopoulos, 1996, 2002; Papaconstantopoulos et al., 1998; Wang et al., 2003; Durgavich et al., 2016).

All elements for which a set of TB parameters have been constructed and for which one has a cubic ground state (except manganese) are presented here. A comparison is made between the results of the TB parametrization and experiment. Calculations were performed at the experimental volume.

The LDA density functional was used for fitting and comparisons, except for those rows marked with an asterisk, which use GGA. All energies are in eV (Mehl and Papaconstantopoulos, 1996).

Energies were computed using a 128-atom supercell. Calculations with the atoms at the primitive lattice sites in the crystal (fixed) and allowing relaxation around the vacancy (relaxed) are shown. First-principles calculations of the vacancy formation energy are given in the column labeled “LDA.” The experimental column shows a range of energies if several experiments have been tabulated. Otherwise, the estimated error in the experiment is given. TB results are from Mehl and Papaconstantopoulos (1996). Experimental data are from Schaefer (1987).

experiment. Aluminum is an intermediate case. It is possible that the measured values are not reliable. Otherwise, there may be a need to check these results against first-principles data and perhaps fit to DFT calculations.

Surfaces

Surface energies are also calculated by a supercell technique (Haftel et al., 2004; Lekka et al., 2003a, 2003b; Mehl and Papaconstantopoulos, 1996). A slab of metal is formed by cleaving the crystal along the desired plane, creating two identical free surfaces. The distance between the two surfaces is increased, creating a set of slabs that repeat periodically in the direction perpendicular to the surfaces. The slabs are separated by a large region of vacuum so that the electrons on one slab cannot hop to a neighboring slab. In addition, the slabs must be thick enough so that the atoms at the center of the slab have the electronic properties of atoms in the bulk material and the two surfaces on the same slab cannot interact with each other. It is found that these criteria are met if slabs containing 25 atomic layers and 7–13 layers between slabs depending on the direction of the surface are used. Care should be taken with respect to the k -point mesh convergence. Depending on the surface and underlying bulk structure, this requires $\sim 200k$ -points in the two-dimensional Brillouin zone. The surface energy, expressed as the energy required to create a unit area of new surface, is then given by the formula

$$E_{\text{surf}} = (E_{\text{slab}} - N E_{\text{bulk}})/(2A), \quad (15)$$

where A is the area occupied by one unit cell on the surface of the slab, E_{slab} is the total energy of the slab, N is the number of atoms in the unit cell, and E_{bulk} is the energy of one atom in the bulk at the lattice constant of the atoms in the interior of the slab. In the first surface calculations, the bulk equilibrium lattice parameters with no relaxation or reconstruction at the surface were used. These calculations showed reasonable agreement with experiment indicating that relaxation does not seriously affect the surface energy. However, recently calculations with all atoms completely relaxed were performed, including charge self-consistency. The new results for Nb (Lekka et al., 2003b) and several f.c.c. metals (Haftel et al., 2004) show significant differences in the interlayer separations and reconstruction.

The results for the f.c.c. metals are particularly gratifying. For the f.c.c. metals, it is found that $E(111) < E(100) < E(110)$, which means that close-packed surfaces are the most stable for the f.c.c. metals. For the b.c.c. metal surface energies, the opposite inequality is satisfied, $E(110) < E(100) < E(111)$.

Stacking faults

Stacking faults are introduced in a crystal by cutting a perfect crystal block along a plane and shifting the upper part with respect to the lower part by a vector f , defining the generalized stacking fault energy surface (Mehl et al., 2000). Local energy minima on this surface are called stable intrinsic stacking faults. In f.c.c. systems and for the (111) slip plane, the stable stacking fault corresponds to a slip of $a/\sqrt{6}$ in the $\langle 112 \rangle$ direction. The $\langle 112 \rangle$ slip is modeled on a (111) slip plane by a supercell consisting of nine close-packed (111) planes of atoms. The primitive vectors of the supercell are

$$\begin{aligned} a_1 &= \frac{1}{2}a\hat{y} + \frac{1}{2}a\hat{z} \\ a_2 &= \frac{1}{2}a\hat{x} + \frac{1}{2}a\hat{z} \\ a_3 &= \left(3 + \frac{q}{6}\right)a\hat{x} + \left(3 + \frac{q}{6}\right)a\hat{y} - \left(3 - \frac{q}{3}\right)a\hat{z} \end{aligned} \quad (16)$$

where q is the stacking fault displacement of the atoms in the boundary layer along the vector f in the $\langle 112 \rangle$ direction. At $q = 0$, the atoms are in f.c.c. positions and at $q = 1$, at the h.c.p. positions. Since the calculations are computationally intensive because of the nine planes of atoms and the 4730 k -points used in the irreducible part of the Brillouin zone, the NRL-TB method proves to be very efficient. The results of the stacking fault energy as a function of the displacement q are shown in Fig. 5. The results correctly predict the qualitative effect that the energies for Ir are much larger than that for the noble metals and they also agree with full-potential linearized muffin-tin orbital (FLMTO) results for Al, Ag and Ir. Finally, the value at the maximum energy in Fig. 5 has been used to extract the unstable stacking fault energy γ_{usf} , which is used together with the surface energy γ_{surf} to establish the Rice criterion for ductility,

$$D = 0.3 \gamma_{\text{usf}}/\gamma_{\text{surf}}. \quad (17)$$

One finds, in agreement with experiment, that the noble metals have the largest values of D .

Phonons

Phonon frequencies at high-symmetry points in the Brillouin zone computed with the NRL-TB model using the frozen phonon approximation are compared with experimentally measured values in Table 5. In this table, results from metals and semiconductors

Fig. 5 Stacking fault energy as a function of the parameter q in [16] for the elemental f.c.c. metals, as determined by the NRL-TB method. The labels γ_{us} and γ_{is} indicate the positions of the unstable and intrinsic stacking faults, respectively, while the f.c.c. label on the left vertical axis indicates the position of the ground-state bulk structure (Mehl et al., 2000).

Fig. 6 Phonon dispersion curves for diamond-structured Si computed from the velocity-velocity correlation function found during a molecular-dynamics simulation at 300 K (solid line) and 1500 K (dashed line) (Bernstein et al., 2000). Dots are taken from experimental data (Tubino et al., 1972).

Fig. 7 Phonon frequencies along high symmetry lines in Ge using the sp^3 basis TB parameters (Bernstein et al., 2002) (solid symbols) compared to DFT/LDA results (Giannozzi et al., 1991) (open symbols) and experiment (crosses) at 80 K (Nelin and Nilsson, 1972).

have been included. The agreement with experiment is similar to that with elastic constants. For most modes the TB results are within 15–20% of experiment, which is also comparable to phonon frequencies obtained directly from first-principles calculations. For some materials, larger errors as for the L_1 and W_2 modes in silicon, and the P and N modes in niobium have been found. This issue has been addressed for Nb (Lekka et al., 2003b) whereby augmenting the first-principles database by including the energies at displacement of 0.005 lattice coordinates for the high symmetry points P and N, the overall fit of the phonon spectrum has been drastically improved. Figs. 6 and 7 show the phonon dispersion curves of Si and Ge that indicate a good agreement with the measured spectra.

Point defects

Point defects in the semiconductors Si (Bernstein et al., 2000) and Ge (Bernstein et al., 2002) have been calculated. Point defects are a major source of disorder in semiconductors since they are thermodynamically favored to occur at finite concentrations and temperatures. Because they are far more mobile than perfectly bonded atoms, they dominate diffusion. The formation energy of such defects strongly influences their concentrations and is, therefore, an important material property.

Table 6 lists the formation energies of three interstitial configurations: the tetrahedral, hexagonal, and 110 split, for Si and Ge. These defect energies were computed using a cubic supercell at the equilibrium lattice constant with 216 atoms, sampling the Brillouin zone at the Γ point. The relaxed configurations were obtained by a conjugate-gradient algorithm using as a criterion the force on each atom to be less than $3 \text{ meV}\text{\AA}^{-1}$. The formation and relaxation energies of all three interstitial configurations are within 10% of the range of LDA calculations for Si but not as good for Ge. On the other hand, the relaxed geometries show more serious discrepancies from *ab initio* results.

Table 6 Formation energies E_f (ideal) and relaxation energies ΔE_f (relaxed), in eV, for point defects computed using the TB model and comparison to DFT/LDA results (Bernstein et al., 2000, 2002).

	TB		LDA		TB		LDA
	E_f^0	E_f	E_f^0	E_f	E_f^0	E_f	E_f
V	Si 4.2	3.2	3.3–4.3	2.9–3.7	Ge 4.6	3.6	1.9
I_t	4.8	4.5	3.7–4.8	3.6–4.6	3.1	2.5	3.2
I_h	5.6	5.1	4.3–5.0	3.7–3.9	5.6	4.4	2.9
$\langle 110 \rangle$	3.7		3.3		4.3	3.3	2.3

Since the structure of the ideal split interstitial is not uniquely defined, the energy listed under ideal is actually the relaxed formation energy.

**Fig. 8** Mean-squared displacement of atoms in diamond-structured silicon as a function of temperature, as determined by TBMD (Bernstein et al., 2000). The dots represent the TBMD data, and the lines are linear (solid) and higher-order representations of the experimental data. From Batterman BW and Chipman DR (1962) Vibrational amplitudes in germanium and silicon. *Physical Review* **127**: 690.

Finite temperature properties from molecular dynamics

The TB method described above can be used with the NRL-TB molecular dynamics (TBMD) package developed by Kirchhoff et al. (2001) to determine thermodynamic properties. For example, the TBMD package can be used to describe computed mean square displacements, and pair correlation functions as a function of temperature, as well as thermal expansion, in silicon, germanium, and gold. It is also possible to extract phonon-dispersion curves from the velocity autocorrelation function determined in an MD simulation.

As an example of the power of the method, one can describe the calculation of the mean-squared displacement of diamond structure silicon as a function of temperature (Bernstein et al., 2000). The calculation used a 512-atom unit cell, evolving at constant energy with fixed initial kinetic energy for 2000 timesteps of length 2.0 fs. As seen in Fig. 8, results are compared with the experimentally determined values, computed from the experimental measurements of the temperature dependence of broadening of the X-ray diffraction peak. The agreement is excellent.

The TBMD code can also determine the change in pressure versus temperature at constant volume. Coupled with the bulk modulus found in Table 1, we can determine the linear coefficient of thermal expansion,

$$\alpha = \frac{1}{3V} \left(\frac{\partial V}{\partial T} \right)_P = \frac{1}{3B} \left(\frac{\partial P}{\partial T} \right)_V \quad (18)$$

Table 7 compares the results for selected elements to experiment.

da Silva et al. (2001) used the NRL-TB parameters for Au to present a very interesting simulation of the formation, evolution, and breaking of Au nanowires.

Multicomponent systems

The above work was confined to single-component systems. The method is extendable to systems with more than one atomic species by making two modifications. First, one adds additional terms to the onsite energies which couple the density from atoms of type i to atoms of type j . Second, one notes that the SK parameters $p\sigma$, $d\sigma$, $dp\sigma$, and $dp\pi$, which in the single-atom case are

Table 7 Linear thermal expansion coefficient α (in K^{-1}) calculated using the TBMD with the NRL-TB parameters for selected elements.

Element	Calculated	Experiment
Ca*	3.07×10^{-5}	2.23×10^{-5}
Sr*	2.45×10^{-5}	2.25×10^{-5}
Be*	1.52×10^{-5}	1.20×10^{-5}
Cu	2.50×10^{-5}	1.80×10^{-5}
Ag	1.07×10^{-5}	2.00×10^{-5}
Au	1.43×10^{-5}	1.40×10^{-5}

The parameters were fit to first-principles LDA calculations except for those elements marked with an asterisk, which are GGA (Chellathurai et al., 2020; McGrady and Papaconstantopoulos, 2021; Silayi et al., 2018).

equivalent (within a sign) to $sp\sigma$, $sd\sigma$, $pd\sigma$, and $pd\pi$, respectively, are now independent parameters. These complications raise the total number of parameters from 93 in the single-atom case, to 330 for two-atom type systems.

This method has been applied to several compounds, including Nb—C, Nb—Mo, Pd—H, Fe—Al, Pt—O, CuZr, Cu—Ag, and Cu—Au (Mehl and Papaconstantopoulos, 1996; Lekka et al., 2009; Silayi et al., 2020). For Cu—Au, the energy of a variety of structures was computed, and it was found that the expected ordered phases (the L_{12} , Cu_3Au , and L_{10} CuAu) were stable, while other structures were not. However, the advantage of the TB model is that one can compare to structures which are not found experimentally, allowing one to explore configurations that might occur locally in an alloy, but which do not form long-range ordered states. To check the correctness of the Cu—Au parameters in this case, it is compared to the cluster-expansion and first-principles calculations of Ozoliņš et al. Fig. 9 shows formation energies computed for several ordered phases in the $\text{Cu}_x\text{Au}_{1-x}$ system and compares them to the energies obtained by Ozoliņš et al. (1998). It is found that the agreement is excellent.

We have also applied the NRL-TB method to understanding the electronic structure of the high-temperature superconductor SH_3 (Drozdov et al., 2015; Papaconstantopoulos et al., 2015). The tight-binding Hamiltonian is a 12×12 matrix including the s, p, and d orbitals of sulfur and three hydrogen s-orbitals. We have simultaneously fitted the energy bands and total energies as a function of volume for the Im3m (superconducting), A15 and L_{12} structures. The total energy (or formation energy) for these three structures is shown in Fig. 10 as a function of volume. The agreement between TB and LAPW is excellent. The energy bands and DOS are shown in Fig. 11 for the bcc-like Im3m structure at the lattice constant $a = 5.6$ Bohr, corresponding to a pressure of 200 GPa where high temperature superconductivity of $T_c = 190$ K has been computationally predicted and observed experimentally. The excellent agreement between TB and LAPW for both bands and DOS is also noted. Table 8 summarizes the DOS at the Fermi level at its decomposition per site and angular momentum the superconducting Im3m structure at a lattice constant of 5.6 Bohr. The strongest contributions to $N(E_F)$ are from the sulfur p- and hydrogen s-states, with a significant contribution from the sulfur d-states.

Fig. 9 Formation energy of several ordered phases in the $\text{Cu}_x\text{Au}_{1-x}$ system, calculated using the TB parameters (blue bars), and compared to first-principles calculations performed by Ozoliņš et al. (1998) (red bars). On this scale, the cluster-expansion energies are indistinguishable from the corresponding LAPW results. For comparison, the first-principles LAPW results (green bars), which were used in the Cu-Au TB fitting process are also plotted.

Fig. 10 Comparison of tight-binding (dashed lines) and LAPW (solid lines) total energies for three phases of SH_3 . Energies and volumes are for one formula unit of each compound.

One- and two-dimensional structures

The NRL-TB method was applied to one- and two-dimensional structures of Cu and Au in conjunction with the conjugate gradient method to study nanoparticles. The TB parameters used (Silayi et al., 2018) were derived by fitting to LAPW calculations of periodic f.c.c., b.c.c., and simple cubic structures. It is impressive that this TB Hamiltonian works well for one- and two-dimensional structures. These TB results are in good agreement with binding energies and bond lengths found by independent first-principles DFT calculations which were not included in the fit. The conjugate gradient method is used to relax the clusters.

Nanoparticles with elongated geometries were made by cutting atoms from the f.c.c. crystalline structure. There are four categories of structures which we labeled A, B, C and D. In category (A) the elongation grows along the [100] direction. In category (B) the elongation is in the [011] direction. In category C the elongation starts with the atoms placed as in (B) and then grows in the [0-11] direction. In category (D) the structure is similar to (A) but it continues along the [1-10] axis. The TB results for binding energy and bond lengths were compared with DFT results for Cu and Au nanoparticles of small number of atoms (between 40 and 60 atoms) where DFT calculations can be done within reasonable computer times. The TB v. DFT comparison was good, motivating us to use the NRL-TB method to perform calculations in larger structures where, due to computational time and memory issues, DFT calculations are problematic. Our TB calculations were able to simulate structures with up to 800 atoms efficiently. The calculation times show that TB is at least three orders of magnitude faster than DFT.

For each category we started with a small structure (for example in category (A), we started with a structure with 40 atoms). Next, we cut the structure in half, moving the two parts in opposite directions. Finally, we add the corresponding atoms to create the largest structure (in this case the structure with 50 atoms, next the structure with 60 atoms, etc.). An important issue in this process was that the nearest neighbor distance of the initial structure must be reasonable (2.6 Ångstrom or smaller) to prevent structure breaking.

The binding energies (BE) per atom for Cu and Au NPs, as calculated with the TB method, are shown in Fig. 12. By comparing with the DFT results for both Cu and Au we find that the TB results follow the same trend as the DFT results. That is, the BE of category (B) has the lowest values, the category (D) follows, and the category (A) has the highest values of all categories. Specifically, the BE energies for Cu with 200 atoms we have: category (A) BE 3.94 eV, category (D) 3.90 eV and category (B) 3.72 eV. The corresponding values for Au are: category (A) 3.29 eV, category (D) 3.27 eV and category (B) 3.22 eV. Furthermore, we observe that the TB BE difference between smaller and larger 0D structures are 1.50 eV for Cu and 1.03 eV for Au. The corresponding results for DFT are 1.20 eV and 0.88 eV for Cu and Au, respectively; a quantitative difference but with the same trend.

After establishing that the TB results for small systems are in good agreement with the DFT ones, larger structures were considered. Fig. 13 shows TB results for Cu NPs of the (D) category. The lengths along the longest direction are 5.18, 7.73, 10.27, 14.39 and 19.26 nm respectively for Cu_{205} , Cu_{304} , Cu_{403} , Cu_{601} and Cu_{808} . Similarly, Au NPs have lengths of 4.79 and 9.78 nm for Au_{205} and Au_{403} respectively. The BE per atom of Cu NPs (with 300 atoms), converge to values of 3.97, 3.92 and 3.84 eV for the (A), (D) and (B) categories respectively. The corresponding saturated BE values for Au NPs (with 300 atoms), are 3.284, 3.287 and 3.220 eV for the (A), (D) and (B) categories.

Fig. 11 Comparison of the LAPW (solid lines) and tight-binding (dashed lines) electronic structure (a) and density of states (b) for the high-temperature superconductor SH_3 at the cubic lattice constant 5.60 Bohr.

Table 8 Total electronic density of states and the orbital contributions to the DOS at the Fermi level of the Im3m superconducting phase of SH_3 .

$N(E_F)$	S-s	S-p	S-d	H-s
6.05	0.30	2.07	1.62	2.06

This data was extracted from the tight-binding fit at the lattice constant of 5.6 Bohr. The DOS is given in units of states/Rydberg/cell for both spins. The hydrogen s value includes the contributions from all three atoms.

Fig. 12 The Binding Energy per atom of (a) Cu and (b) Au structures, using Tight Binding.

We have also calculated the HOMO-LUMO (HL) Gap and the Density of States (DOS). The TB results are compared with the corresponding DFT results in Fig. 14 for the HL gap and Fig. 13 for the DOS showing good agreement. We note that the HL gap for the smaller structures have higher values compared to the HL gap for the larger structures. This happens due to the transition from semiconductor to metallic behavior. This transition occurs at about 30–50 atoms systems. Generally, the HL gap of DFT has somewhat lower values compared to TB. For DFT, the values of the HL gap for Cu_{25} (category D) and Cu_{80} (category B) structures are 0.69 eV and 0.10 eV, respectively. The corresponding values for TB are 0.75 eV and 0.18 eV. This discrepancy is probably due to the following two factors: (a) the TB parameters used result from a fit to LAPW results from periodic cubic structures where the exchange and correlation functional (Hedin-Lundqvist) is different than that in the DFT code, and (b) different temperature broadening parameters used in the respective methods for calculating the DOS.

In Fig. 15 we show the per one atom DOS for different sizes of Cu and Au systems (24 and 108 atoms). The per one atom DOS shown are similar, characterized by the dominant d- states of Cu and Au, below the Fermi level and very small s-like DOS values at E_f reminiscent of the DOS of bulk periodic Cu. The DOS for small number of atoms shows a gap at the Fermi level (see Cu_{24} and Au_{24} in Fig. 14). For larger systems like Cu_{108} and Au_{108} , this gap is filled by s-like states. Furthermore, we calculate the per one atom DOS for the Cu_{601} and Cu_{808} cases. The graphs for those cases are similar to the corresponding Cu_{108} graph.

Fig. 13 The Copper structures over 200 atoms, that grow along the $[110]$ direction (category D), using Tight Binding. More specifically, (a) Cu_{205} , (b) Cu_{304} , (c) Cu_{403} , (d) Cu_{601} and Cu_{808} .

Fig. 15 The DOS per one atom for (a) Cu_{24} —category B, (b) Cu_{108} —category B, (c) Cu_{808} —category D, (d) Au_{24} —category B and (e) Au_{108} —category B.

Conclusion

We have shown that the NRL-TB method generates TB Hamiltonians that fit very well first-principles electronic structure results such as LAPW energy bands, density of states and total energies for most elements in the periodic Table and several compounds. This scheme accurately determines the ground state and the equilibrium lattice parameter of the system and positions well the total energies of other structures that were not included in the fit. Also, mechanical properties like elastic constants and bulk moduli as well as phonon frequencies are found in good agreement with experiment without being included in the database of the original fit. Large scale molecular dynamics simulations give a good account of mean-squared displacements, vacancy formation energies and the coefficient of thermal expansion, with a much smaller computational cost than most first-principles calculations. It should be emphasized that the NRL-TB approach is successful in obtaining a wide spectrum of properties unlike other TB or empirical potential schemes which usually have a restricted range of applications.

Introduction

Understanding the electronic structure of solids is basic to explaining and predicting solid-state properties, but what is an appropriate description of electronic states in solids?

Although it is clear that solids are made of atoms and that one can think of the gas-to-liquid-to-solid transitions as a process in which atoms just get closer together, the electronic properties of solids often differ significantly from what one would expect from a collection of isolated atoms. In cases where the interactions between the atoms are weak, as in the case of rare gas solids, it is reasonable to consider these interactions as perturbations of atomic states. However, when atoms are close to each other in a solid, sometimes they can give up their outermost electrons easily, and it is even possible to end up with a sea of nearly free electrons. In fact, a nearly free-electron model is appropriate for metals such as the alkali metals, aluminum, and many others.

It is also fortunate and useful that this nearly free-electron model applies to a wider class of solids when a few modifications are added. A totally free electron is described by a plane-wave wave function. Hence, if one assumes that the electrons describing a metal behave as if they are nearly free, then a plane-wave position-dependent wave function $\Psi(\mathbf{r})$ confined to a box of volume Ω , having a wave vector ($\mathbf{k}$) which can be written as

$$\psi(\mathbf{r}) = \frac{1}{\sqrt{\Omega}} e^{i\mathbf{k} \cdot \mathbf{r}}$$

may be a good starting point for describing the electrons in metals such as sodium. If one examines the resulting electronic density corresponding to a plane-wave wave function, it is constant since it is proportional to $\psi^*(\mathbf{r})\psi(\mathbf{r})$. Therefore, the collection of atoms with localized wave function on each atomic site and peaked electronic density yields a valence electron density which is vastly different.

What about bonds? For example, covalent bonds arise because electrons tend to concentrate in certain regions between atoms. Can the bonds and charge modulation known to exist in metals and especially in covalent semiconductors be described using plane waves as a starting point? The answer is yes for a broad class of solids. A plane wave is a solution to Schrödinger's equation when the electron-ion and electron-electron potentials are zero. However, when these potentials are included (and if they are not too strong and if the electrons are not strongly correlated), a perturbative scheme can be used to modify the free-electron picture, and this is the "nearly free-electron model" which is described in many textbooks. However, more generally, Schrödinger's equation is solved by diagonalizing a Hamiltonian matrix with appropriate potentials and a basis set composed of plane waves to describe the wave function.

What about alternatives to the nearly free-electron model? The opposite approach to using plane waves is the utilization of atomic wave functions for the basis set. There are tight-binding methods where linearized combinations of atomic orbitals form the basis. This description is also very useful especially when the solid-state wave functions are not too different from the atomic wave functions forming them. If done correctly with sufficient orbitals in the basis set, both the above methods work and are useful.

In the following discussion, the plane-wave basis is featured. In particular, a pseudopotential-density functional approach is described which has been applied successfully to a large number of solids, clusters, nanostructures, and molecules.

The Standard Model of Solids

In Figure 1, a schematic picture of a solid is presented where the nuclei and core electrons for the atoms are represented as positive cores and the stripped-off valence electrons are contributed to the electron sea which flows through the periodic array of cores. In this model, the solid system is viewed as having two types of particles: cores and valence electrons. The interaction between the positive cores is taken to be a standard Coulomb interaction describable by Madelung sums. The electron-core and electron-electron interactions are essential inputs to this model. As mentioned above, the form of the standard model of solids, represented by Figure 1, which is focused here, will model the electron-core interaction using pseudopotentials and the electron-electron interaction using the density-functional theory – in particular, the local density approximation (LDA).

Figure 1 Schematic view of a solid with positive cores at fixed lattice positions in a periodic array and a sea of relatively free valence electrons moving through the lattice.

Pseudopotentials

Arguments for the use and/or appropriateness of a weak electron–core potential have been made since the 1930s. In 1934, Fermi constructed a pseudopotential to describe highly excited electronic states of alkali atoms. His weak potential was designed to yield an accurate description of the outer portions of the wave function and to avoid the more difficult calculation of the properties of the oscillations of the wave function near the core. This would require a strong potential. Since solid-state effects are dominated by the outer portions of atomic wave functions, this is a viable approach for constructing pseudopotentials for solids. As shown in Figure 2,

Figure 2 The solid line represents the Si 3s pseudo-wave-function resulting from the use of a pseudopotential. The dashed line results from an “all electron” calculation.

a “pseudoatom” wave function is generated which is identical to an “all-electron” 3s radial wave function for Si away from the core and smooth near the core. The weak pseudopotential which produced the pseudoatom wave function can be computed from first principles using only the atomic number as input. There are many schemes available for producing these *ab initio* pseudopotentials, which in principle can be constructed for all atoms.

The electron–electron interactions can be approximated using the electronic density. This density-functional approach represents the Hartree and exchange-correlation potentials as functionals of the electronic density. Hence, a self-consistent calculation can be done with a plane-wave basis set, pseudopotentials, and the LDA to density-functional theory. The calculated electronic density can be used to produce LDA potentials which in turn can produce updated wave functions and subsequently, new LDA potentials. This scheme and variants using pseudopotentials and plane waves are often referred to as the “plane-wave pseudopotential method” (PWPM). In general, the method has been extremely successful for determining the electronic structure and many other properties of solids.

Although most modern pseudopotential calculations use *ab initio* pseudopotentials of the type described above, the pseudopotential method went through a semi-empirical stage of development where experimental input was used to generate a potential representing the total valence electron potential (electron–core plus electron–electron). This approach, called the empirical pseudopotential method (EPM), used plane waves and a few Fourier coefficients of the potential which were fit to experimental data. In addition to explaining the origin of the optical structure in the visible and UV in terms of interband electronic transitions and many other properties of solids, the EPM set the stage for the first-principles methods and the standard model.

A schematic real space potential is illustrated in Figure 3. The strong ionic Coulomb potential is “cut off” in the core region. The physical origin of the cancelation of the ionic potential in the core region was attributed by Phillips and Kleinman to a repulsive potential arising because of the Pauli exclusion principle preventing the valence electrons from occupying core states. The result is again a weak net potential describable by a few Fourier form factors and a wave function which can be expanded in a plane-wave basis set. Usually, three pseudopotential form factors per atom gave highly accurate electronic band structures.

The EPM was the first successful plane-wave method for real materials with applications to metals, semiconductors, and insulators. Dozens of band structures and optical response functions were calculated with high precision for the first time. The optical spectra of semiconductors were interpreted in terms of critical points in the electronic band structure, and when the wave functions were used to compute the electronic density, the covalent and ionic bonds were pictorially displayed – again for the first time.

In Figure 4, a plot of the predicted electronic density for Si is displayed and compared with results based on subsequent X-ray studies. In addition to the striking agreement between theory and experiment, these plots reveal the nature of the covalent bond. It is particularly satisfying to see the local build-up of charge in the Si–Si bond region even though the basis set is composed of plane waves which yield a constant density before the potential is “turned on.” There is no prior prejudice for this pile-up of charge in the bond region built into the basis set.

Total Energy Calculations and Structural Properties

The EPM calculations were constructed to deal with bulk crystals which were not terminated. Standard techniques, described in textbooks, use periodic boundary conditions to avoid having surfaces or interfaces. The EPM pseudopotential $V(r)$ has the periodicity of the lattice so it could be expressed as an expansion using reciprocal lattice vectors G :

$$V(r) = \sum_G S(G) V(G) e^{iG \cdot r}$$

where $S(G)$ is the structure factor that locates the atoms relative to a lattice point. It is the form factors $V(G)$ which are fit to experiment in the EPM scheme.

In order to deal with surfaces and interfaces, one has to allow charge to redistribute at a surface or interface and break translational invariance. To do this, the EPM evolved into a scheme where the electron–core and the electron–electron potentials were separated. As in modern calculations, the electron–core potential is referred to as the “pseudopotential” and the electron–electron potential was expressed in terms of the density. In early calculations, the Slater and Wigner approximations were used. This allowed the charge density to readjust to a surface or interface and because of self-consistency, so did the potentials. The surface or interface was modeled by introducing a supercell which contained the geometric configuration of interest. For example, a (1 1 1) Si surface was modeled using a slab containing 12 atomic layers separated from the next slab by an equivalent space with no atoms. The surface of the slab represented the surface of the Si crystal and self-consistency required the rearrangement of the electronic density to correspond to the new geometry. Figure 5 shows this rearrangement of electron density on an ideal Si (1 1 1) surface in one of the first calculations done with this method. Later calculations used supercells to examine Schottky barriers, heterojunctions, and reconstructions at surfaces and interfaces.

The evolution of the use of the LDA was straightforward since in this approach the electron–electron potentials are expressed as functionals of the electron density. Hence, surfaces, interfaces, and localized configurations in general could be dealt with using supercells and by letting the charge density adjust to the geometric constraints. The use of the PWPM and the LDA also allowed the exploration of other solid-state properties.

Important applications became possible once a scheme was developed to calculate the total structural energy E_s of the solids for given configurations of the atomic cores. Once E_s is evaluated for a series of candidate structures, a comparison of their structural energies immediately reveals the lowest energy structure for the group. At a given volume, this lowest energy structure would be the

Figure 5 Valence electron density for the ideal Si (1 1 1) surface. Contours are plotted in the perpendicular (1 1 0) plane with units corresponding to one electron per primitive cell. The shaded disks represent atomic cores.

most stable structure if all possible structures are considered. Since it is not possible to test all structures, a limitation on this method is the possible omission of the most stable structure. However, in practice, it has often been possible to choose the most likely structures, and the success rate of the PWPM is high for predicting new structures and structural properties. Because E_S depends on volume (or lattice separations), changes induced by pressure can cause solid–solid phase transitions where crystal structures can change. Therefore, calculations of the dependence of on volume can predict transition pressures and volumes for the structural phase changes. Similar calculations for lattice constant changes caused by strains or alloying can yield elastic constants and even vibrational spectra.

Using the standard model with cores and valence electrons as illustrated in Figure 1, the total structural energy of the solid can be expressed as

$$E_S = E^{cc} + E^{ec} + E_k^e + E_c^{ee} + E_x^{ee}$$

and all the energy components can be evaluated using the PWPM. The core–core Coulomb energy E^{cc} can be calculated from point–ion sums as discussed earlier, E^{ec} is evaluated using the pseudopotential, and both the Hartree (Coulomb) electron–electron energy E_c^{ee} and the exchange–correlation energy E_x^{ee} can be approximated using the electron density. The electron kinetic energy E_k^e is obtained once the wave function is computed. Therefore, with pseudopotentials and the LDA approximation, the total energy E_S and many ground-state properties can be determined for different structural configurations.

It is convenient to evaluate the above energy contributions to E_S using expressions for the potentials and energies in reciprocal space. An early application was the examination of the ground-state properties of Si. Figure 6 contains the results for calculations of E_S as a function of volume for seven candidate structures. The volume is normalized by the experimental volume of the diamond phase at atmospheric pressure. Therefore, when the volume is unity, this corresponds to ambient pressure and the diamond phase has the lowest energy. As the pressure increases and the volume decreases, it is noted that the hexagonal diamond-structured material is always at a higher energy than the diamond (cubic) structure; therefore, diamond is the more stable phase. At smaller volumes (higher pressures), the β -tin phase has a lower energy than diamond-structured Si, and β -tin is therefore the stable phase. If one views the transition as occurring along the dashed line (Figure 6) which is the common tangent between the diamond and β -tin curves, the transition volumes (points 2 and 3) can be evaluated along with the transition pressure which is the slope of the common tangent. These values are all found to be in good agreement with the measured data. In addition, the minimum energy volume for the diamond structure yields a calculation of the equilibrium lattice constant while the curvature of E_S as a function of volume near the minimum energy point yields the bulk modulus or compressibility for Si. In all the calculations, it is assumed that the temperature is zero.

Using the above method, the lattice constants and bulk moduli have been calculated for many solids. Typical accuracies are less than 1% for lattice constants and less than 5% for bulk moduli. Discrepancies between theory and experiment for transition volumes and pressures are normally in the few percent range. In addition, modifications of structures at interfaces and surfaces can

Figure 6 Structural energies for seven structures of Si as a function of volume normalized to the experimental volume at ambient pressure (solid lines). The common tangent represented by the dashed line illustrates the structural transition between the diamond and β -tin structures.

also be addressed with this approach. By calculating the changes in energy with movements of specific atoms or by computing Hellmann–Feynman forces, it is possible to determine reconstructions of surfaces and interfaces. In the calculations described above, the only input is the atomic number of the constituent atoms to calculate the pseudopotential and the candidate structure.

Another important application of this method is the determination of vibrational spectra. The method often used within the PWPM is called the “frozen phonon” approach, where the crystal structure is distorted to represent the displaced atoms associated with a particular phonon mode. By comparing the energies of the undistorted and distorted structures or by directly calculating the forces on the atoms, the phonon spectrum can be determined. Here, one needs to input the atomic masses of the constituent atoms as well as their atomic numbers. Again, agreement with experiment is excellent.

Superconductors, Optical Properties, and Novel Materials

A particularly striking success of this approach is its application to superconductivity. The systems considered are expected to be “BCS electron–phonon superconductors.” A variation on the frozen phonon method allows a determination of the electron–phonon coupling constants. As described above, the PWPM within the LDA yields ground-state properties with high precision. Since the superconducting transition temperature in the BCS description is extremely sensitive to the strength of the electron–phonon parameter λ and, to a lesser extent, the Coulomb parameter μ^* , it is imperative that the normal-state properties of the material studied be known with high precision. Only a few first-principles calculations of μ^* are available; however, this parameter does not vary a great deal for different materials, and it scales reasonably well with the density of states at the Fermi energy. In contrast, λ can have a much larger variation and therefore the focus for first-principles calculations for superconducting materials has been on the determination of λ .

The enhancement of the effective mass is also related to λ :

$$m^* = m_b(1 + \lambda)$$

where m_b is the band mass calculated without including the electron–phonon interactions. The strong dependence on λ for the superconducting transition temperature, T_c , can be illustrated by equations such as the McMillan equation which have the generic form

$$T_c = AT_D \exp\left(\frac{1}{\lambda^* - \mu^*}\right)$$

where A is a constant, T_D is the Debye temperature, and $\lambda^* = \lambda/(1 + \lambda)$.

The PWPM formulation for the calculation of λ had as its first application a study of high-pressure phases of Si. The results were dramatic because the existence of the two high-pressure solid metallic phases, simple (or primitive) hexagonal (s.h.) and hexagonal close packed (h.c.p.) were predicted by PWPM calculations. In addition to predicting the transition pressures needed to obtain these phases, their electronic, structural, vibrational, and superconducting properties were successfully predicted. The input information was only the atomic number and atomic mass of Si, the candidate structures, and an estimate of μ^* .

Although the PWPM has limited use for highly correlated materials, it is sometimes used as a starting point to obtain the electronic structure before correlation effects, such as a Hubbard U parameter, are considered to estimate the expected changes when correlation is considered. However, when new superconductors are found, it is common to apply the approach described above as a test of whether one is dealing with a conventional superconductor or not. Superconducting doped C_{60} materials, nanotubes, and MgB_2 are good representatives of materials in this category.

The case of MgB_2 serves as an excellent example of what can be done now with the PWPM and Eliashberg theory, which is an extension of the BCS theory. The method yielded the electronic and vibrational properties of MgB_2 and demonstrated that the strongest electron–phonon coupling was associated with a particular phonon mode. By considering phonon anharmonicity and including the anisotropy of the superconducting energy gap which was found to be important when doing the calculation, it was possible to reproduce the experimental data and predict new properties. The results were consistent with the proposal that MgB_2 is a BCS superconductor with electron pairing caused by electron–phonon coupling and that the superconducting energy gap was multivalued. The results for MgB_2 are particularly striking since this PWPM calculation had no experimental input except for the estimate of μ^* and the known structure of MgB_2 .

The optical properties of solids are of particular interest when one is describing a method for computing an electronic structure. The interplay between the development of quantum mechanics and the study of atomic optical spectra was extremely important to the evolution of both fields. However, identifying peaks in optical response functions for solids appeared to be a formidable task. Unlike atomic spectra that contained very sharp peaks which could be interpreted in terms of electronic transitions between narrow electronic states, solid-state spectra were broad and featureless.

The challenge remained in essence until the 1960s, and, for the most part, it was the use of the EPM which provided the tools to deal with these spectra, particularly for semiconductors. An important feature is the fact that peaks in optical response functions, such as reflectivity, arise from interband transitions between states where the bands are parallel. For example, if an electron in a valence band n at point k in the Brillouin zone with energy $E_n(k)$ is excited to an empty state m with energy $E_m(k)$, this requires a photon having energy $\hbar\omega = E_m(k) - E_n(k)$. This transition will result in a more prominent structure or “signature” in the reflectivity if the initial occupied and final unoccupied bands are parallel at the point k . The condition is $\nabla_k E_n(k) = \nabla_k E_m(k)$, and this is the requirement for a “critical point” to occur in the band structure. It can be shown that this critical point is associated with the structure in the joint density of states between the two bands. This structure, referred to as a Van Hove singularity, in turn, appears in the optical response functions such as the reflectivity or frequency-dependent dielectric function. It was the analysis of these critical points in semiconductor spectra that yielded the energy separations used to fit the pseudopotential form factors for the EPM. A typical result is shown in Figure 7 where the modulated or derivative reflectivity spectrum of Ge is displayed. Derivative spectroscopy is used to accentuate the Van Hove structures, and the zeros and peaks arise because of the nature of the critical points. As discussed before, the positions of these are related to the energies of the critical points. In Figure 7, near the 2 eV region, it is noted that although there is reasonable agreement between theory and experiment for the critical point energies, the magnitudes of the curves differ considerably. This arises because of electron–hole attraction effects which are not included in the calculation. These are discussed later.

Figure 7 The modulated or derivative reflectivity spectrum for Ge. A comparison is made between the experimental spectrum and the theoretical calculation.

Although the transition from the EPM to *ab initio* PWPM applications was fairly straightforward, there were particularly interesting problems associated with the calculations of energy-band separations, the minimum bandgap, optical spectra, and the role of electron-hole effects described above. The most dramatic signal that one could not just apply the LDA and the PWPM to obtain experimental band structures was the fact that researchers using this approach were consistently underestimating bandgaps. The specific focus was on Si where the measured and EPM values for the minimum gap were 1.1 eV, while the PWPM-LDA gap was half this value. The EPM was fit to give the correct result, but the *ab initio* method had as its input the LDA, the pseudopotential, and the plane-wave bases. It was soon found that other methods using the LDA gave similar results. Hence, it was concluded that it was the use of the LDA which resulted in calculations which underestimated the bandgap. Since it was emphasized by the inventors of the LDA that, in principle, this approximation should not be applicable for bandgap determination, this result came as no surprise. However, because of the ease of use of the LDA and its success for determining ground-state properties, it was hoped that modifications could be made to standard LDA methods to allow the computation of bandgaps and optical spectra.

A successful practical solution to this dilemma that was often referred to as “the bandgap problem” involved the use of the “GW” method. In this approach, the quasiparticle energies appropriate to excited electron and hole states are calculated starting with LDA calculations. In this scheme, the electron self-energy is computed using the Green’s function G and a screened Coulomb potential W . When the resulting self-energy is included in the LDA calculation, the electronic states are renormalized and yield bandgaps in excellent agreement with experiment for a broad class of materials. An analysis of the results of applying the GW method reveals that two important physical features are mainly responsible for the success of the method. First, by using an appropriate dielectric function which includes local field effects, the variations in the charge density arising because of bonding effects are correctly included. Second, the renormalization of the electronic energies because of their interactions with plasmons and electron-hole excitations is included to produce appropriate quasiparticle states produced because of the excitations.

Hence with the inclusion of GW modifications to the LDA, the calculations employing the PWPM can yield bandgaps and band structures in agreement with experiment on a level of accuracy found for the experimentally fit EPM results. In addition, these *ab initio* calculations have been extended further and have addressed the problems of the effects on the optical response functions arising from electron-hole interactions. This problem was raised earlier when discussing the results shown in Figure 7. Modifications of spectra of this kind are sometimes referred to as exciton enhancements of oscillator strengths near band edges. However, even when excitons, which are bound states of electron-hole pairs, are not formed, the electron-hole interactions in the excited state can still modify the oscillator strengths and in turn the optical response functions. Applications of the Bethe-Salpeter approach for two-particle interactions to this problem with electron and hole wave functions computed using the PWPM have been successful. At this point, applications of the GW approximation including electron-hole effects have been done for several materials. The computational requirements are somewhat heavy, but the results in all cases tested yield excellent spectra.

A major and important component of condensed matter physics is the research focused on the development of new and novel materials. In the past two or three decades, new systems have revealed new physical properties, new physics, and important application. Systems such as superlattices, fullerenes, nanotubes, and high-temperature superconductors have broadened the horizons. Often novel materials are complex, structurally or electronically, and they offer new challenges for theoretical methods such as the PWPM. In particular, the number of atoms in a unit cell or supercell is a constraint on this method. Usually, complex materials or configurations of materials can only be modeled with a large number of atoms, and this may require a very large number of plane waves in the basis set. If the electronic structure results in very localized configurations as might be appropriate for complex molecules, again many plane waves may be required. A further and interesting aspect of most novel systems on the nanoscale level is that there are effects of confinement. These effects can be dominant for lower-dimensional or very small structures, and they must be accounted for in the calculational scheme.

A typical example is the case of research on nanocrystals where there have been significant advances in recent years. Here, supercells can be employed along with the PWPM. Other techniques which start out with plane waves have had success. One such approach is to use the EPM to generate Bloch functions for a bulk crystal and then convert these itinerant states into more localized states represented by Wannier functions. If the nanocrystal is then modeled using a potential which is bulk-like inside the nanocrystal and zero outside, the Wannier functions can be used to solve the resulting Hamiltonian appropriate to the nanocrystal. One example of the application of this method is a study of the bandgap of InAs as a function of the nanocrystal radius. The results are in excellent agreement with experiment.

Many applications of the PWPM to C_{60} and nanotubes have appeared in the literature. Electronic structure calculations for C_{60} were used to interpret optical, photoemission, superconducting, and other properties. For nanotubes, the explorations have been even more extensive. For carbon nanotubes, calculations of the properties of semiconductor and metal nanotubes have revealed interesting aspects of their electronic structure for interpreting transport and optical properties. Theoretical predictions of Shottky barrier and heterojunction systems composed of semimetallic and semiconductor nanotubes have been verified. There is even evidence of superconductivity which is consistent with semi-empirical calculations based on PWPM results. No completely *ab initio* calculations of the superconducting properties of fullerenes or nanotubes as in the case of MgB_2 have as yet been done.

A dramatic success of applications of the methods described here to this area is the successful prediction of compound nanotubes. In particular, the prediction of BN nanotubes was verified. In this case, unlike the situation for carbon nanotubes, all BN nanotubes without defects or impurities are semiconducting independent of their “chirality.” Theory also suggests that when doped, BN nanotubes will have interesting behavior. An example is the nature of the free electron-like wave function associated with the lowest conduction band for this system. It is predicted that when doped appropriately, the electron density for this state will reside in the center of the BN nanotube. It is expected that this system will resemble a tube with electrons filling its center. Other

interesting predictions are that, for BC_2N nanotubes, doping can result in electrons traveling along a spiral path producing effects resembling a nanocoil. For BC_3N , it is expected that each tube will behave as if it were a semiconductor, but a collection of these tubes would be metallic. Although the existence of these predicted compound nanotubes has been established, in general, their transport properties have not been measured, so tests for these unusual predicted properties will have to wait until the appropriate experimental techniques become available.

Conclusion

Summarizing, the history of the use of plane-wave methods for electronic structure calculations has many components. As was discussed, the physical justifications came in different forms, and the development of the techniques required physical interpretation. For example, the major changes in the development of the PWPM were motivated by the desire to answer new questions or to broaden the application of the method. Although the advances in computer hardware had a large effect, the largest impact came from the knowledge gained from doing the calculations. It is important to know what is important, or as Linus Pauling said, "The secret to having good ideas is to have many ideas and the judgment to know which ones should be discarded."

Abstract

The collective oscillations of electrons in monolayer and bilayer graphene show different characteristics from those in ordinary two-dimensional Fermi gases. The chirality of the electrons in graphene sets up extra selection rules to their dynamics. The unconventional energy dispersion relation in graphene modifies the electron movement. The narrow gap encourages the carrier exchange between the conduction and the valence bands. The competition between the intra- and the inter-band interactions may introduce extra plasmon branches. The potential bias between the sublattices in monolayer graphene and the monolayers in bilayer graphene opens gap in the electron-hole single particle continuum. Undamped plasmon modes with almost zero group velocity may appear in the gap.

Key points

- Coulomb screening and collective excitations of electrons in monolayer and bilayer graphene are studied in the random phase approximation.
- Physical mechanism behind the evolution of plasmon spectra in parameter spaces are described.
- Approaches to manipulating the plasmon spectra in graphene are proposed.
- Optimized conditions for undamped plasmon modes with low group velocity are discussed.

Introduction

Mobile electrons in a charge neutral solid material may be a plasma system with negative charges immersed in a uniform background of equal and opposite positive charges. An external charge therein redistributes the negative charges and result in an electric field different from that in vacuum. This Coulomb screening effect can be described by the dielectric function $\epsilon(\omega)$ which relates the modified electric field E and the electric field in vacuum or the electric displacement D by $E = D/\epsilon$ at frequency ω . Collective plasma oscillations may be excited spontaneously at some specific plasma frequency ω_p if $\epsilon(\omega_p) = 0$. As in the case of a simple harmonic oscillator, the energy of each plasma oscillation is quantized into units of $\hbar\omega_p$ according to the quantum mechanics. The corresponding quasi particles with the energy unit are known as plasmons Yu and Cardona (2003). In an ordinary two-dimensional electronic Fermi gas (2DEG), an effective mass m^* can be used to describe the energy dispersion of the electrons as $E = \hbar^2 k^2 / 2m^*$, and $\omega_p^{2D} = [ne^2 q / 2\epsilon_0 \epsilon_b m^*]^{\frac{1}{2}}$ in the long wavelength limit $q \sim 0$ (Ando et al., 1982). Here k is the electronic wave vector, n is the sheet density of the electron gas, q is the wave vector of plasmon, ϵ_0 is the permittivity of vacuum, and ϵ_b is the background high-frequency dielectric constant. An electron gas in graphene may differ from the normal Fermi gases in at least three aspects, the energy dispersion, the chirality, and the energy gap between the conduction and the valence bands. The random phase approximation (RPA) for many-body Coulomb interaction can be employed to describe approximately the screening effect and understand the behavior of plasmons in graphene as in normal Fermi gas (Castro Neto et al., 2009; Abergel et al., 2010; Das Sarma et al., 2011; Goerbig, 2011; Kotov et al., 2012; Vafeek, 2006; Wang and Chakraborty, 2007a, b, 2010; You and Wang, 2012; Hwang and Das Sarma, 2008).

The RPA Coulomb interaction in the Fourier space $V(q, \omega)$ obeys the equation

$$V(q, \omega) = v_0 + v_0 \hat{\Pi}_0(\mathbf{q}, \omega) V(q, \omega) \quad (1)$$

with the electron-hole propagator

Fig. 1 Diagrammatic illustration of the RPA dressed Coulomb interaction.

$$\hat{\Pi}_0(\mathbf{q}, \omega) = 4 \sum_{\lambda, \lambda', \mathbf{k}} \left| g_{\mathbf{k}, \lambda'}^{\lambda}(\mathbf{q}) \right|^2 \frac{f[E_{\mathbf{k}+\mathbf{q}}^{\lambda'}] - f[E_{\mathbf{k}}^{\lambda}]}{\omega + E_{\mathbf{k}+\mathbf{q}}^{\lambda'} - E_{\mathbf{k}}^{\lambda} + i\delta}, \quad (2)$$

as illustrated by the Feynmann diagram in Fig. 1. Here the factor 4 comes from the degenerate two spins and two nonequivalent valleys K and K' of honeycomb lattice in graphene, $f(E)$ is the Fermi-Dirac distribution function for electrons of energy E , $v_0 = e^2/(2\epsilon_0\epsilon_F q)$ is the two-dimensional bare Coulomb interaction (in Fourier space) (Peres et al., 2005), the index $\lambda = \pm$ marks the conduction and valence bands, $g_{\mathbf{k}, \lambda'}^{\lambda}(\mathbf{q})$ is the Coulomb interaction vertex factor which depends on the electron wave functions. The plasmon spectrum can be obtained by finding the zeros of the real part of the dielectric function

$$\hat{\epsilon}(q, \omega) = 1 - v_0(q) \hat{\Pi}_0(\mathbf{q}, \omega). \quad (3)$$

The imaginary part of the dielectric function gives the damping rate of the collective excitations to the electron-hole single-particle excitations (Mahan, 2000).

Plasmons in monolayer graphene

Monolayer graphene (MLG) has a honeycomb lattice of carbon atoms with two sublattices A and B. The two sublattices are displaced from each other along an edge of the hexagons by a distance of $a_0 = 1.42\text{\AA}$. Its energy band can be calculated by the tight-binding model and an intrinsic graphene is a semimetal with the Fermi energy located at the nonequivalent K and K' points at opposite corners of its hexagonal Brillouin zone (Wallace, 1947; Slonczewski and Weiss, 1958; Zunger, 1978; Ando, 2002). In the effective mass approximation, the Hamiltonian of electrons near the Fermi energy is expressed by a 8×8 matrix. In the case of spin and valley degeneracies, the matrix can be reduced to four independent 2×2 blocks. In the representation of the two sublattices, the Hamiltonian of a spin-up electron near the K point of the reciprocal space reads

$$H^{mg} = v_{mg} \mathbf{p} \cdot \boldsymbol{\sigma} + \Delta \sigma_z = \begin{bmatrix} \Delta & v_{mg} p_- \\ v_{mg} p_+ & -\Delta \end{bmatrix}, \quad (4)$$

with $\boldsymbol{\sigma} = (\sigma_x, \sigma_y, \sigma_z)$ the Pauli matrices in the pseudospin space of the two sublattices and $p_{\pm} = -\hbar(\partial/\partial x \pm i\partial/\partial y)$ (Kane and Mele, 2005; DiVincenzo and Mele, 1984; Sinitsyn et al., 2006). Here $v_{mg} = 10^6$ m/s is the 'light' velocity of the Dirac electron gas in MLG. 2Δ is the potential bias between the two sublattices, which is zero in intrinsic graphene but can be nonzero in graphene grown on substrates like boron nitride.

The eigenenergy and eigenfunction of the above Hamiltonian read

$$E_k^{\lambda} = \lambda \sqrt{\Delta^2 + \hbar^2 v_{mg}^2 k^2}, \quad (5)$$

$$\Psi_k^{\lambda} = e^{i\mathbf{k} \cdot \mathbf{r}} \begin{pmatrix} \sin[\alpha_k/2 + (1 + \lambda)\pi/4] \\ -\cos[\alpha_k/2 + (1 + \lambda)\pi/4] e^{i\phi_k} \end{pmatrix} \quad (6)$$

with $\tan\phi_k = k_y/k_x$, $\tan\alpha_k = \hbar v_k/\Delta$, and $k = \sqrt{k_x^2 + k_y^2}$. The interaction vertex factor reads $|g_{\mathbf{k}, \lambda'}^{\lambda}(\mathbf{q})|^2 = [1 + \lambda\lambda' \cos\alpha_{\mathbf{k}+\mathbf{q}} \cos\alpha_k + \lambda\lambda' \sin\alpha_{\mathbf{k}+\mathbf{q}} \sin\alpha_k \cos\theta]/|\mathbf{k} + \mathbf{q}|/2$ with θ being the angle between $\mathbf{k}$ and $\mathbf{q}$. Since the intra-band backward scattering at $\mathbf{q} = 2\mathbf{k}$ and the inter-band vertical transition at $\mathbf{q} = 0$ are not allowed under Coulomb interaction in the system, we have $|g_{\mathbf{k}, -\lambda'}^{\lambda}(0)|^2 = |g_{\mathbf{k}, \lambda'}^{\lambda}(2\mathbf{k})|^2 = 0$.

In intrinsic MLG, the net electron density is equal to zero and $E_F = 0$. There exists no plasmon mode at zero temperature. Fig. 2A and B show the real (ϵ_r) and imaginary (ϵ_i) parts of the dielectric function at temperature $T = 0$ for $\Delta = 0$ (solid), 0.08 (dashed), and 0.1 meV (dotted) at a wave vector $q = 0.05 \times 10^5 \text{ cm}^{-1}$. At zero temperature, only inter-band transitions are allowed for electrons. The electron-hole propagator for $\Delta = 0$ is given by $\hat{\Pi}_0(\mathbf{q}, \omega) = -q^2/[4\sqrt{\hbar^2 v_{mg}^2 q^2 - \omega^2}]$ (J. González et al., 1994, 1999, 2001; Khveshchenko, 2006). Therefore we have $\epsilon_r = 1$ (for $\omega > \hbar v_{mg} q$) above the interband electron-hole continuum (EHC) edge and $\epsilon_i = 0$ (for $\omega < \hbar v_{mg} q$) below it. With increasing Δ , the peaks of ϵ_r and ϵ_i , which are located at the edge of the interband EHC, $\omega_H = 2\sqrt{\Delta^2 + \hbar^2 v_{mg}^2 q^2}/4$, shift to higher energies. At the same time, for $\omega > \omega_H$, ϵ_r increases continuously with Δ and remains positive.

At a finite temperature, the intra-band transitions are allowed and contribute to the electron-hole propagator of Eq. (2) and a ϵ_r dip at the intra-band EHC edge $\omega_L = \hbar v_{mg} q$ is formed as shown in Fig. 2C. For $\Delta = 0$ where $\omega_L = \omega_H$, two plasmon modes may

Fig. 2 Real (ϵ_r) and imaginary (ϵ_i) parts of the dielectric function vs ω in MLG at $T = 0$ (left panels) and $T = 2$ K (right panels) for $E_F = 0$ and $\Delta = 0$ (solid), 0.08 meV (dashed), and 0.1 meV (dotted). The wave vector is $q = 0.05 \times 10^5 \text{ cm}^{-1}$.

appear, one strongly Landau damped at $\omega = \hbar v_{mg}q$ and another weakly damped at a higher energy. The damping rates of the plasmon modes are indicated in Fig. 2D by ϵ_i at the corresponding energies. Comparing the curves in Fig. 2D with those in (B), at finite temperatures a finite ϵ_i at $\omega < \omega_L$ is introduced by the intra-band transition and a decreased ϵ_i for $\omega > \omega_L$ due to the weakening of the inter-band transitions, a result of the electronic occupation of the conduction band. With increasing Δ , the ϵ_r peak shifts with ω_H to higher energy while the ϵ_r dip stays with ω_L . Since the ϵ_r peak has a lower energy than the ϵ_r dip initially at $\Delta = 0$, the peak and the dip merge at first and split again. As a result, at temperature $T = 2$ K as shown in Fig. 2C, the ϵ_r curve for $\Delta = 0.08$ meV is deformed in such a way that two extra zeros of ϵ_r or two new plasmon modes emerge. Corresponding to the separation of the ϵ_r peak from its dip, the ϵ_i curve evolves a gap between ω_L and ω_H as illustrated in Fig. 2D. One of the plasmon modes is located in this ϵ_i gap or the EHC gap and is undamped, and so it can be observed experimentally. For $\Delta = 0.1$ meV, there is no damped plasmon mode in the inter-band EHC.

The appearance of the undamped plasmon mode in the existence of energy gap is a result of the interplay between intra- and inter-band correlations which can be adjusted by varying the temperature of the system in experiments. For an MLG of $\Delta = 0.08$ meV, with increasing temperature from $T = 0$, the ratio of the intra to the inter-band correlation increases and ϵ_r in the EHC gap ($\omega_L \leq \omega \leq \omega_H$) decreases and crosses zero. There is no plasmon mode when inter-band correlation dominates at $T \leq 1.1$ K and only two damped modes exist when the intra-band correlation dominates at $T \geq 3.3$ K. In the temperature regime $1.1 \text{ K} \leq T \leq 3.3 \text{ K}$ or $T \approx 2\Delta$ when the intra- and inter-band correlations can match with each other, however, $\epsilon_r(\omega_L) < 0$ while $\epsilon_r(\omega_H) > 0$ and one undamped plasmon mode exists. Furthermore, in the upper end of this regime at $1.9 \text{ K} \leq T \leq 3.3 \text{ K}$, one undamped mode and three damped modes exist.

The ω versus q spectrum of the plasmon modes at $T = 2$ K is plotted by thick solid curves for $\Delta = 0$ in Fig. 3A and for $\Delta = 0.08$ meV in Fig. 3B. The weakly damped plasmon mode in the $\Delta = 0$ case has an approximate dispersion of $\omega \propto \sqrt{q}$ at small q . A finite Δ separates ω_H from ω_L and opens a gap between the intra- and inter-band EHC's. As a result, the formerly weakly damped plasmon mode becomes undamped near $q = 0$ because it is now located in the gap. When it approaches the inter-band EHC edge, the dispersion curve of this mode is squeezed to a lower energy by the ϵ_r peak near the inter-band EHC edge as shown in Fig. 2C and then is split into three plasmon modes, viz., two new plasmon modes emerge near the inter-band EHC edge. One of the modes remain undamped in the EHC gap and the other Landau damped two are located inside the inter-band EHC. The latter two modes merge and disappear at q near $0.07 \times 10^5 \text{ cm}^{-1}$ for $\Delta = 0.08$ meV. The undamped mode survives in larger wavevectors until it merges with the strongly damped mode to the intra-band EHC edge when the inter-band correlation dominates and ϵ_r becomes positive in the all frequency regime. The insets of Fig. 3 show the excitation spectral weight or the dynamical structure factor $S(\mathbf{q}, \omega) = -(1/nv_0(q))\text{Im}[1/\hat{\epsilon}(\mathbf{q}, \omega)]$ at $q = 0.05 \times 10^5 \text{ cm}^{-1}$ (Mahan, 2000; Hwang and Das Sarma, 2008). The damped plasmon spectra is hidden in the EHC's while the undamped plasmon spectra appears as a sharp peak in the EHC spectral gap and should be observable in experiments (Grimes and Adams, 1976).

As discussed above, dominant intra-band correlation results in the appearance of the plasmon mode with dispersion $\omega \propto \sqrt{q}$ at small q in Dirac gases as well as in Fermi gases (Stern, 1967). Different from 2DEGs, Dirac gases of $E_F = 0$ show only inter-band correlation at zero temperature and there is a strong competition between intra- and inter-band correlations as the parameters of the system vary. Controlling the sublattice bias and the carrier density can change significantly the ratio between intra- and inter-band many-body correlations of the Dirac electron gas and may introduce undamped plasmon modes (Novoselov et al., 2005; Zhang et al., 2005).

Fig. 3 Plasmon spectrum (thick curves) of MLG ($E_F = 0$) at temperatures $T = 2$ K with $\Delta = 0$ in (A) and 0.08 meV in (B). Intra- (dark shaded) and inter- (light shaded) band single-particle continua are also shown. ω_L and ω_H are the lower and upper borders separating the white (EHC gap) and shaded areas respectively in (B). The vertical dotted lines indicate the q values for which excitation intensity is shown in the insets and the dielectric function is shown in Fig. 2C.

Due to the symmetry of the band structure, MLG having the same density of electrons or holes are similar and the result can be shown by a system with a net electron density and positive Fermi energy E_F . For a Dirac gas in a MLG, the extra electrons in the conduction band reduce the inter-band scattering rate but enhances the intra-band one by increasing the length of the Fermi ring. Similar to the case of finite temperature, a plasmon mode with an approximate dispersion $\omega \propto \sqrt{q}$ at small q appears even at zero temperature as shown in Fig. 4A. For $\Delta = 0$ and at $T = 0$, a EHC gap of width $2\hbar v_{mg}(k_F - q)$ is opened above the intra-band EHC edge in the range $0 < q < k_F$. This EHC gap at finite Fermi energy lets the $\omega \propto \sqrt{q}$ plasmon mode undamped near $q = 0$. Another character of this mode at finite fermi energy is its flat dispersion slope as shown by the dashed curve in Fig. 4A, compared with the case at finite temperature as shown in Fig. 3A, near its entrance into the interband EHC. Furthermore, in contrast to the emergence of new plasmon modes occurred when its dispersion curve enters the inter-band EHC from a EHC gap, the dispersion curve enters the inter-band EHC smoothly here. We can characterize the carrier density by the Fermi energy to emphasize the interesting energy regime in the existence of energy gap. The corresponding carrier density can be estimated with the help of their simple relation at zero temperature $n = (E_F^2 - \Delta^2)/(\pi v_{mg}^2)$. For example, the carrier density of a system with $E_F = 1$ meV is $n = 7.34 \times 10^7 \text{ cm}^{-2}$.

The presence of the energy gap changes the physical scenario of the excitation spectrum in the $\Delta = 0$ case described above. At $T = 0$, the intraband EHC edge deviates from $\omega = \hbar v_{mg}q$ to a lower energy $\sqrt{\Delta^2 + \hbar^2 v_{mg}^2 (k_F + q)^2} - \sqrt{\Delta^2 + \hbar^2 v_{mg}^2 k_F^2}$, the inter-band EHC edge shifts to a higher energy $\sqrt{\Delta^2 + \hbar^2 v_{mg}^2 k_F^2} + \sqrt{\Delta^2 + \hbar^2 v_{mg}^2 (k_F - q)^2}$ for $q < 2k_F$ while remains ω_H when $q > 2k_F$.

Fig. 4 The same as in Fig. 3 with $E_F = 0.25$ meV at $T = 0$ (A) and $T = 2$ K (B). The solid curves are for $\Delta = 0.08$ meV and the dashed in (A) for $\Delta = 0$. The inset of (B) shows the zoomed area where the $\sqrt{q}$ plasmon mode enters the interband EHC and splits into three modes.

More interestingly, the sublattice bias may shift the plasmon mode in the interband EHC to the EHC gap and makes it undamped. For a system of $E_F = 0.25$ meV, the plasmon mode at $q = 0.05 \times 10^5 \text{ cm}^{-1}$ becomes undamped if $\Delta > 0.02$ meV. In a MLG of $\Delta = 0.08$ meV, the plasmon mode remains undamped up to $q = 0.1 \times 10^5 \text{ cm}^{-1}$ where it merges with the mode in the intra-band EHC as illustrated by the solid curves in Fig. 4A.

At higher temperature the restriction to single-particle transitions by the Fermi energy is relaxed and the EHC is independent of the Fermi energy as shown by the shades in Fig. 3B and Fig. 4B. However, the collective excitation spectrum changes as the ratio of intra- to interband correlation increases with the net electron density. The relative weakening of inter-band correlation when $E_F > \Delta$ lowers the ε_r peak at the inter-band EHC edge, shown in Fig. 2C, and consequently changes the number or shifts the position of the zeros of ε_r for different q . Comparing the resulting plasmon spectrum plotted in Fig. 4B with that in Fig. 3B, we find that for q between $0.006 - 0.04 \times 10^5 \text{ cm}^{-1}$ the undamped mode disappears because the ε_r peak becomes lower than zero and for q bigger than $0.07 \times 10^5 \text{ cm}^{-1}$ two damped modes exist in the inter-band EHC.

Plasmons in bilayer graphene

The bilayer graphene (BLG) is formed by stacking two graphene monolayers in the same way as the stacking occurs in graphite, i.e., the Bernal stacking (McCann and Fal'ko, 2006; Koshino and Ando, 2006; Nilsson et al., 2006; Ohta et al., 2006). The two graphene monolayers are arranged in such a way that the A sublattice is exactly on top of the sublattice B' with a vertical separation of $b_0 = 3.4 \text{ \AA}$ (Trickey et al., 1992). The system can be described by a tight-binding model characterized by three coupling parameters, $\gamma_0 = 3.16$ eV between the atoms A and B or A' and B' (intra-layer coupling), $\gamma_1 = 0.39$ eV between A and B' (the direct inter-layer coupling), and $\gamma_3 = 0.315$ eV between A' and B, A and A', or B and B' (the indirect inter-layer coupling) (Koshino and Ando, 2006).

In the k space, the BLG has the same hexagonal Brillouin zone as that of a monolayer. Its physical properties are mainly determined by the energy spectrum and the wavefunction near the two inequivalent corners of the Brillouin zone K and K' , where the π^* conduction band and the π valence band meet at the Fermi surface (Wallace, 1947). Due to the strong interlayer coupling (the π orbit overlap) both the conduction band and the valence band in a bilayer are split by an energy of ~ 0.4 eV near the K and K' valleys (Trickey et al., 1992; Yoshizawa et al., 1996; Ohta et al., 2006). Since this energy splitting is larger than the energy range we are interested in from the bottom of the energy band, we take into account only the upper valence band and the lower conduction band. The BLG cannot be treated as two independent graphenes monolayer with the interlayer coupling as a perturbation because of the strong interlayer overlap of the π orbits. In contrast, the perturbation treatment of the interlayer coupling is valid for a normal double quantum well system or in an intercalated graphite (Wang, 2005; Shung, 1986; Visscher and Falicov, 1971).

In the effective-mass approximation (McCann and Fal'ko, 2006; Koshino and Ando, 2006), the electrons in the K valley are described by a Hamiltonian with a mixture of the linear and the quadratic terms of p

$$H^{bg} = \frac{\hbar^2}{2m^*} \begin{pmatrix} 0 & p_-^2 \\ p_+^2 & 0 \end{pmatrix} - \frac{\hbar^2 k_{bg}}{2m^*} \begin{pmatrix} 0 & p_+ \\ p_- & 0 \end{pmatrix}. \quad (7)$$

The effective mass of the quadratic term is $m^* = 2\hbar^2\gamma_1/(3a_0\gamma_0)^2 \approx 0.033m_0$ with m_0 the free electron mass and the 'light' velocity of the linear term is $v_{bg} = \hbar k_{bg}/2m^* = 3a_0\gamma_3/2\hbar \approx 10^5 \text{ m/s}$ with $k_{bg} \approx 10^8/\sqrt{3} \text{ m}^{-1}$.

The eigenenergy and eigenfunction of the above Hamiltonian read

$$E_k^\lambda = \lambda \hbar^2 k \sqrt{k^2 - 2k_{bg}k \cos 3\phi + k_{bg}^2/2m^*}, \quad (8)$$

$$\Psi_k^\lambda(\mathbf{r}) = \frac{e^{i\mathbf{k}\cdot\mathbf{r}}}{\sqrt{2}} \begin{pmatrix} e^{i\varphi_k} \\ \lambda \end{pmatrix}. \quad (9)$$

with the pseudospin angle $\lambda\varphi_k = \lambda \arg(k e^{-2i\phi} - k_{bg} e^{i\phi})$. Here $\arg(z)$ is the argument θ of a complex $z = |z| e^{i\theta}$.

For $k \gg k_{bg}$ the electron states are chiral with $\varphi = -2\phi$ and have an approximately isotropic parabolic energy dispersion $E_k^\lambda = \lambda \hbar^2 k^2/2m^*$. Near $k = k_{bg}$, the energy dispersion becomes highly anisotropic as shown in Fig. 5A and B. The corresponding characteristic energy is $E_0 = \hbar^2 k_{bg}^2/2m^* = 3.9$ meV. At $E = 0$, where the Fermi energy is located in the undoped BLG, there are four contact points between the conduction and the valence bands: One at $k = 0$, the center of the valley and the three satellites at $k = k_{bg}$ in the directions of $\phi = 0, 2\pi/3$, and $4\pi/3$. They can be treated as four Dirac points because the electronic states near each point have a linear energy dispersion and have the same chirality as those near a Dirac point in the monolayer graphene. However, compared to the monolayer graphene, the energy dispersion here is anisotropic and the 'light' velocity is about 10 times slower. As illustrated in Fig. 5A and B, there is an energy pocket with a depth of about $E_0/4$ at each Dirac point. The above peculiar characteristics of the BLG makes it quite different from the MLG in their Coulomb screening properties as described in the following.

The Coulomb interaction vertex factor reads $|g_k^{\lambda,\lambda'}(\mathbf{q})|^2 = [1 + \lambda\lambda' \cos(\varphi_k - \varphi_{k+q})]/2$. Near the central Dirac point at $k = 0$, the intraband backward scattering and interband vertical Coulomb scattering are forbidden and $|g_k^{\lambda,-\lambda'}(0)|^2 = |g_k^{\lambda,\lambda'}(-2\mathbf{k})|^2 = 0$. The same rules also hold for the three satellite Dirac points. For a large $k(k \gg k_{bg})$, $|g_k^{\lambda,-\lambda'}(0)|^2 = |g_k^{\lambda,-\lambda'}(-2\mathbf{k})|^2 = 0$ but $|g_k^{\lambda,\lambda'}(-2\mathbf{k})|^2 = 1$, i.e. the intraband backward transition is allowed but both the interband backward and vertical transitions are forbidden. The above selection rules together with the energy dispersion of the carriers in the BLG indicate that the electrons (holes) close to the bottom (top) of the conduction (valence) band have very different behaviors from those away from the bottom (top).

Fig. 5 (A) The contour lines of the energy in the $k_x - k_y$ plane near the K point in BLG. The corresponding energies, starting with the innermost curve are $0.1E_0$ to E_0 with an increment of $0.1E_0$. (B) The energy spectrum for equally separated ϕ from 0 to $\pi/6$ (curves with increasing energy).

Note that in a MLG the dielectric function $\hat{\epsilon}$ is invariant if all the parameters with the energy unit, ω , E_F and $k_B T$, and with the wavevector unit, k and q , vary proportionally because of the linear energy dispersion of the Dirac gas (Wang and Chakraborty, 2007a). As a result, the dielectric function and the plasmon dispersion is uniform for systems with proportional parameters. In a BLG, however, this is not true anymore because of the nonlinear energy dispersion.

The static dielectric function at zero temperature versus q is plotted in Fig. 6A. Its long wavelength limit is given by the properties of the four Dirac points. The central point has an isotropic ‘light’ velocity v_{bg} while the satellite ones have the elliptic form of equi-energy lines with a minimum ‘light’ velocity equal to v_{bg} along their radial direction and a maximum of $3v_{bg}$ along the azimuthal direction. The static dielectric constant at $q = 0$ is estimated to be $\epsilon_s = 1 + 3e^2/(8\epsilon_0\hbar v_{bg}) \approx 105$. This value is much bigger than that of the MLG (4.5) (Wang and Chakraborty, 2007a). This means that the long-range Coulomb interaction is much more strongly screened for the bilayer system, thanks to a much bigger density of states near the Fermi energy in a BLG.

Another characteristic of the BLG is its screening anisotropy, especially for scattering at a distance range of about 10 nm. This is shown by the difference between the solid and the dotted curves in Fig. 6, corresponding to the directions of q pointing to any satellite from the central Dirac points ($\alpha = 0$) or connecting any two satellites ($\alpha = \pi/6$) respectively. Here α is the angle between q and the x -axis. At $q = \sqrt{3}k_{bg} = 10^8 \text{ m}^{-1}$, the wavevector distance between any two satellite Dirac points, the anisotropy of ϵ_s reaches its maximum with a mismatch of 20% along the different directions. The shoulder near $q = k_{bg} = 0.58 \times 10^8 \text{ m}^{-1}$ in the solid curve reflects the strong scattering between the carriers in the central and the $\phi = 0$ satellite Dirac points. At a finite temperature, the energy pockets near the Dirac points are partially occupied and the intraband scattering strength is greatly enhanced. As a result, the static dielectric function near $q = 0$ increases rapidly, as shown in Fig. 6B at $T = 4.2 \text{ K}$. The real and imaginary parts of the dynamic dielectric function versus the energy for a small wavevector $q = 0.005$ along $\alpha = 0$ at $T = 0$ and at $T = 4.2 \text{ K}$ are shown in Fig. 6C and Fig. 5D.

Fig. 6 (A) The static dielectric function ϵ_s vs the wavevector q in BLG along the direction $\alpha = 0$ (solid) and $\pi/6$ (dotted) at $T = 0$. (B) The same as (A) but at $T = 4.2 \text{ K}$. (C) The real part of the dielectric function ϵ_r vs frequency ω at $T = 0$ (dotted) and at $T = 4.2 \text{ K}$ (solid). (D) The imaginary part of the dielectric function ϵ_i vs ω at $T = 0$ (dotted) and at $T = 4.2 \text{ K}$ (solid). In (C) and (D), $q = 0.005 \times 10^8 \text{ m}^{-1}$ and $\alpha = 0$. In the limit $\omega \rightarrow \infty$, ϵ_r gradually approaches to one while ϵ_i approaches to zero.

For $\omega > E_0/2$, the dielectric function of a BLG is similar to that of a normal Fermi gas and its temperature dependence is weak. The step of ϵ_r and the peak of ϵ_i near $\omega = E_0/2 = 2$ meV correspond to the single-particle excitation coupling states with a vanishing group velocity and having wavevectors located near the middle between the central and the satellite Dirac points. For small ω , however, the dielectric function becomes more sensitive to the temperature and shows characteristics of the Dirac gas. One sign of the Dirac gas is the lack of Coulomb screening ($\epsilon_r \approx 1$) in the energy window between 1 and 2 meV. Another sign is that a low-energy plasmon mode appears only at a finite temperature. As shown in Fig. 6C, the ϵ_r has no negative value for the energy $\omega < E_0/2$ at $T = 0$ but evolves into a deep negative dip at a finite temperature $T = 4.2$ K, when the energy pockets near the Dirac points is partially occupied. As a result, one observes a weakly Landau damped plasmon mode of dispersion $\omega \sim \sqrt{q}$ at $T = 0$ and may observe two such weakly damped modes at finite temperatures.

Fig. 7A presents the plasmon spectrum of an intrinsic BLG ($E_F = 0$). The dispersion of the weakly Landau damped mode is indicated by the thick curve and has a $\sqrt{q}$ dependence. Interestingly, the plasmon mode exists only at the energy higher than $E_0/2$, i.e., double the depth of the energy pockets in the Dirac points. At a finite temperature $T = 4.2$ K, another weakly damped plasmon mode appears at the energy lower than $E_0/2$ and also has a dispersion of $\sqrt{q}$ near $q = 0$, as illustrated in Fig. 7B. The plasmon mode of higher energy that exists at $T = 0$ is not sensitive to the temperature. This temperature dependence of the low and high energy plasmon spectra represents the marked difference between the electron gases having linear (without the collective excitation) and quadratic (with the collective excitation) energy dispersion at $T = 0$. We have established earlier that the collective excitations appear only at a finite temperature for the Dirac gas (Wang and Chakraborty, 2007a). The electronic states in a BLG are similar to the Fermi type at the high energies but reverts to a Dirac type at the low energy.

The carrier density of the system can be changed by doping. For a typical doping density of 10^{12} cm^{-2} , the Fermi energy is high enough from the conduction bottom and the linear k term in the Hamiltonian can be neglected (Koshino and Ando, 2006; Ohta et al., 2006). The electrons then have a quadratic dispersion but with chirality and $\varphi = -2\phi$. Near $q = 0$, the plasmon dispersion in a doped BLG has again a $\sqrt{q}$ dispersion as shown by the solid curve in Fig. 8 and shares the same dispersion with a normal 2DEG. The effect of the chirality is shown by the dotted curve for the plasmon dispersion of a normal two-dimensional Fermi gas with two valleys, for comparison. The two curves overlap for the small q but separate as q increases. The maximum difference in the dispersion appears near $q = \sqrt{2}k_F$ when $\mathbf{k}$ and $\mathbf{k} + \mathbf{q}$ form a right angle in the Fermi plane and the corresponding transition is forbidden in the BLG due to its chirality.

Plasmon in biased bilayer graphene

Under a perpendicular electric field, an energy gap opens between the conduction and the valence bands in BLG (McCann and Fal'ko, 2006), when an electrostatic potential bias U exists between the two graphene layers. In the effective-mass approximation, the Hamiltonian describing electrons of moderate energies in the K valley of a biased BLG reads

$$H^{bbg} = \frac{\hbar^2}{2m^*} \begin{pmatrix} 0 & p_-^2 \\ p_+^2 & 0 \end{pmatrix} + \frac{U}{2} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \quad (10)$$

Fig. 7 The plasmon spectrum of intrinsic BLG at $T = 0$ (A) and at $T = 4.2$ K (B). The thick curves indicate the weakly Landau damped modes while the thin curves represent the strongly damped modes.

Fig. 8 The plasmon spectrum of a doped BLG (solid curve) with a typical carrier density of 10^{12} cm^{-2} , corresponding to $E_F = 36.3 \text{ meV}$ and $k_F = 1.77 \times 10^8 \text{ m}^{-1}$. The plasmon spectrum in the same system but without chirality is plotted as a dotted curve for comparison. Intra- (dark shaded) and inter- (light shaded) band single-particle continua are also shown.

The indirect inter-layer coupling is neglected since it affects only the energy band in the range of less than 2 meV from the middle of the conduction-valence band gap. The eigenenergy and eigenfunction of the above Hamiltonian read

$$E_k^{\lambda} = \lambda \sqrt{\left(\frac{\hbar^2 k^2}{2m^*}\right)^2 + \left(\frac{U}{2}\right)^2}, \quad (11)$$

$$\Psi_k^{\lambda} = e^{ik \cdot r} \begin{pmatrix} \sin[\beta_k/2 + (1 + \lambda)\pi/4] \\ -\cos[\beta_k/2 + (1 + \lambda)\pi/4] e^{i2\phi_k} \end{pmatrix}. \quad (12)$$

Here β_k indicates the ratio of the kinetic energy to the potential bias with $\tan\beta_k = \hbar^2 k^2 / (m^* U)$. For such an energy dispersion the DOS of the system is

$$D(E) = \frac{1}{(\pi)^2} \int \frac{dS}{|\nabla_k E|} = \frac{m^*}{\pi \hbar^2} \frac{E}{\sqrt{E^2 - (U/2)^2}}, \quad (13)$$

Under finite bias U , the DOS of the BLG diverges on the edge of the energy gap $E = |U/2|$. The vertex factor reads

$$\left| g_k^{\lambda, \lambda'}(\mathbf{q}) \right|^2 = \left| \langle \mathbf{k} + \mathbf{q}, \lambda' | e^{iq \cdot r} | \mathbf{k}, \lambda \rangle \right|^2 = \frac{1}{2} \left[1 + \lambda \lambda' \cos \beta_k \cos \beta_{k+q} + \lambda \lambda' \sin \beta_k \sin \beta_{k+q} \cos(2\phi_k - 2\phi_{k+q}) \right].$$

When $\mathbf{q} = 0$ and $\mathbf{q} = -2\mathbf{k}$, $\left| g_k^{\lambda, \lambda'}(\mathbf{q}) \right|^2 = \frac{1}{2} (1 + \lambda \lambda')$. Similar to unbiased BLG, the interband vertical and back scatterings are both forbidden but the intraband back scattering is allowed in biased BLG. For intraband scattering with $\mathbf{k} \perp \mathbf{k} + \mathbf{q}$, we have $\left| g_k^{\lambda, \lambda'}(\mathbf{q}) \right|^2 = \frac{1}{2} [1 + \cos(\beta_k + \beta_{k+q})]$, which becomes zero in unbiased BLG.

The intraband component ($\lambda = \lambda'$) of the electronhole propagator is expected to be similar to that in normal 2DEG except the effect of chirality and deformation of energy band. The interband one ($\lambda = -\lambda'$), which can be manipulated by the bias voltage, modifies qualitatively the screening properties of the system. Since the approximate energy spectrum we use in this study is isotropic, the obtained properties are also isotropic and we use $q \equiv |\mathbf{q}|$ and $k \equiv |\mathbf{k}|$ in the following discussion.

Fig. 9 shows the negative intraband propagator in unit of $N_0 = 2m^*/\pi$ (the DOS of intrinsic BLG) versus frequency ω for three typical wavevector q values. Similar to the 2DEG result at zero temperature, the imaginary part is nonzero in the single-particle continuum $0 < \omega < \omega_u$ for $0 < q < 2k_F$ and $\omega_l < \omega < \omega_u$ for $q > 2k_F$, with $\omega_l = |E_{k_F-q}^{-1} - E_{k_F}^{-1}|$ and $\omega_u = E_{k_F+q}^{-1} - E_{k_F}^{-1}$. The derivative of the imaginary part is not continuous at the continuum edges and for $0 < q < 2k_F$ is also not continuous at $\omega = \omega_l$ besides $\omega = 0$ and ω_u . When the bias U increases, the structures of the curves shift to lower energy because the energy band is narrowed and the group velocity of electrons at the bottom of the conduction band decreases. When the temperature increases, the sharp edges become smoother and the nonzero range gets wider as expected.

Different from the 2DEG result, as illustrated in Fig.9C for $q > k_F$ at $U = 0$ and $T = 0$, the imaginary part has a sharp dip with a derivative discontinuity at $\omega_m = q^2/2m^*$ between the edges due to the chiral nature of the wave functions (Sensarma et al., 2010). The dip and discontinuity persist at finite temperature but become softened and disappear under finite bias voltage.

The real part, presented in the lower panels of Fig.9, shows a sharp peak at ω_l and a sharp dip at ω_u with an extra peak near ω_m for $q > k_F$ and moves in a similar way as the imaginary part with bias and temperature. However, the structure near ω_m for both the imaginary and real part develops in a different way from those at ω_l and ω_u when U and T increase. It remains at high temperature and removes off with the bias voltage while those at ω_l and ω_u decay with temperature. On average, the variation range of the propagator decreases with q .

Fig.11 illustrates the negative interband propagator in unit of N_0 versus ω for the same three q values as in Fig.10. Its imaginary part and the single-particle continuum have a minimal energy limit $\omega_1 = E_{k_F}^{-1} - E_{k_F-q}^{-1}$ at zero temperature or $\omega_2 = 2E_{q/2}^{-1}$ at finite

Fig. 9 The negative intraband electron-hole propagator in unit of N_0 versus frequency ω in unbiased/biased BLG at zero/room temperature. The imaginary part for $q = 0.06, 0.8$, and $2.5k_F$ is plotted in panel (A), (B), and (C), respectively, and the corresponding real part in (D), (E), and (F). The electron density is $n = 10^{12} \text{ cm}^{-2}$ with the Fermi wavevector $k_F = 1.77 \times 10^8 \text{ m}^{-1}$. The corresponding Fermi energy is $E_F = 34 \text{ meV}$ at $U = 0$ and $E_F = 45.4 \text{ meV}$ at $U = 60 \text{ meV}$. Solid curves are for $T = 0, U = 0$; dashed $T = 0, U = 60 \text{ meV}$; dotted $T = 300 \text{ K}, U = 0$; dash-dotted $T = 300 \text{ K}, U = 60 \text{ meV}$.

Fig. 10 The negative interband electron-hole propagator of BLG in unit of N_0 versus frequency ω is plotted for the same parameters set and arrangement as in Fig.9.

temperature. For small q [Fig.10A] the imaginary part increases sharply and reaches a peak before decreases in a way $\sim 1/\omega$. For mediate $q = 0.8k_F$ [Fig.10B] the main peak becomes round and smooth while a sharp peak near $\omega_3 = E_{k_F}^1 - E_{k_F+q}^{-1}$ appears under bias as shown in the inset of Fig.10B. This latter peak grows and becomes more visible as U increases. For $q > k_F$ a peak with discontinuity appears near $\omega_m = q^2/2m^*$ at zero temperature in both biased and unbiased BLG as shown in Fig.10C (Sensarma et al., 2010).

Corresponding to the continuum edges of the imaginary part, on the curve of the real part as shown in the lower panels of Fig.10, there is a peak near $\omega_1(\omega_2)$ at low (high) temperature when the electron system is degenerate (nondegenerate). The peak near ω_2 may become very sharp for small q in biased BLG because the bottom (top) of the conduction (valence) band becomes flat and the DOS diverges on the edge of energy gap. The overall contribution of interband excitation to the propagator increases with q and in a way $\sim q^2$ at small q .

The electron-hole propagator reflects the electric polarizability of a many-body system screening a Coulomb potential. After being reduced by the background dielectric constant ϵ_b , it determines the dielectric function $\epsilon(q, \omega) = \epsilon_r + i\epsilon_i$. The zero of the real part ϵ_r gives the collective excitation of the system in the absence of external electromagnetic field. The imaginary part ϵ_i gives the spectrum of the single-particle excitation. In the presence of only intraband single particle excitation as in conventional 2DEG, there exist maximally two plasmon modes, one acoustic mode of frequency ω_A within the single-particle excitation and another optical mode ω_O , because $-Re[\Pi(q, \omega)]$ has only one dip below zero as shown in Fig.9. The acoustic mode is thus always overdamped with little spectral weight and not experimentally relevant. The contribution from interband excitation introduces fine structures to ϵ_r near zero and at least two extra modes, ω_3^p and ω_4^p may emerge.

Fig. 10 displays ϵ_r versus ω for various temperature T (A), bias voltage U (B), electron density n (C), and wavevector q (D). In the high frequency limit, the effect of polarization vanishes and $\epsilon_b = 1$. For intrinsic BLG where $n = 0$, the intraband polarization is negligible and $\epsilon_r > 0$ at $T = 0$. There is no collective mode. In other cases, the ϵ_r versus ω curve has a deep dip at ω_u and a peak at ω_1 or/and ω_2 . The competition among value one, the intra-, and the inter-band contributions to the polarizability determine its fine features. For typical parameters, as illustrated in Figs. 9 and 10, the effect of the intra-(inter-) band polarization decreases (increases) with q so we expect that ϵ_r mainly shows intra- (inter-) band characteristics for long (short) wavelength. In this study we are mostly interested in the screening and collective excitation properties of long wavelength in the system, and in Fig.11 we present the details only for $q \ll k_F$ near $\epsilon_r = 0$.

The result for a system of $U = 30$ meV, $n = 10^{12} \text{ cm}^{-2}$, and $q = 0.1 \times 10^8 \text{ m}^{-1}$ is exhibited in Fig.11A. At low temperature $T = 4$ K (solid) when the system is degenerate, the intraband contribution dominates and a peak appear near $\omega_1 = E_{k_F}^1 - E_{k_F-q}^{-1} \simeq 2E_{k_F}^1 = 74.4$ meV which is out of the panel. When the temperature increases to 200 K (dashed) and the system becomes nondegenerate, a sharp peak emerge near $\omega_2 = 2E_{q/2}^1 \simeq 30$ meV. Since this interband peak is located just below the optical

Fig. 11 The real part of the dielectric function ϵ_r vs frequency ω when $\epsilon_b = 1$ in variety of the BLG bias U , temperature T , electron density $n (\times 10^{12} \text{ m}^{-2})$, and wavevector $q (\times 10^8 \text{ m}^{-1})$ is plotted in (A)–(D), respectively. Parameters $U = 30$ meV $n = 10^{12} \text{ m}^{-2}$, $q = 0.1 \times 10^8 \text{ m}^{-1}$, $T = 300$ K are used if not specified in the panels.

plasmon energy ω_O , it can introduce two extra roots ω_3^b and ω_4^b to the equation $\varepsilon_r = 0$, i.e., two extra plasmon modes in the system. The extra plasmon mode of lower energy ω_3^b is out of the interband single-particle continuum and can be only weakly damped. When the temperature increases further (dotted and dash-dotted) the enhanced intraband contribution shifts the peak below zero and the extra plasmon modes disappear. In the same time, ω_O increases with the temperature as more electrons (holes) exist in the conduction (valence) band.

As shown in Fig.11B, the bias voltage can sensitively shift the interband peak and control the emergence of the extra plasmon modes. These modes have energies (frequencies) proportional to the bias voltage and group velocities close to zero. The increase of the electron density enhances the degeneracy of the system and reduces the amplitude of the interband peak at $\omega_2 = 2E_{q/2}^1$ as plotted in Fig.11C. The enhanced intraband contribution at higher density also increases the frequency of the optical plasmon mode ω_O .

Fig.1D illustrates how the $\varepsilon_r - \omega$ curve develops with q at room temperature $T = 300$ K. Overall the intra-(inter-) band contribution to ε simply decreases (increases) with q as shown previously in Figs.10 and 11, but their effect on the plasmon spectrum is more complicated due to their competition with each other. When q increases, the intraband introduced ε_r dip becomes wide which usually results in the increase of the plasmon frequency. The interband peak of ε_r is located at the fixed energy $\omega_2 \simeq 30$ meV and its amplitude increases with q . As a result, only when ω_2 is close to ω_O , the interband contribution can affect significantly the plasmon spectrum.

The plasmon spectrum in intrinsic BLG (unbiased and undoped) depicted in Fig.12 at various temperatures T (A) and for various background dielectric constant ε_b (B). At zero temperature, there is no carrier and no plasmon mode in the system. At finite temperature, electrons (holes) are excited in the conduction (valence) band and two plasmon modes emerge. In the long-wavelength limit, their frequencies are proportional to $\sqrt{T}$ at high temperature. Similar to the 2DEG result, we also observe a dispersion $\omega_O \propto \sqrt{q}$ and $\omega_A \propto q$. The background dielectric constant can also be employed to modify the plasmon frequency as shown in Fig.12B. The acoustic mode is not sensitive with ε_b but the frequency of optical mode decreases quickly with ε_b .

In Fig. 13, the plasmon spectrum for various electron densities at zero temperature is illustrated in unbiased BLG (A) and in biased one with $U = 60$ meV (B). In the long-wave limit, $q \sim 0$, the dielectric function is dominated by the intraband contribution. The properties of the system at zero temperature is mainly determined by the group velocity of electrons at the Fermi energy. The plasmon spectrum of unbiased system is similar to that of 2DEG. If the electron density is not high, e.g. $n \lesssim 10^{12} \text{ cm}^{-2}$ for $U = 60$ meV as shown in Fig.13B, the Fermi group velocity of electrons decreases when the external electric field is turned on, due to the band deformation, and the plasmon mode is softened. With increasing q the interband contribution becomes more important, which reduces the group velocity of the optical plasmon mode. In some cases, the group velocity of plasmon can be close

Fig. 12 Plasmon spectrum of intrinsic BLG (A) in vacuum with $\varepsilon_b = 1$ at various temperature and (B) with various dielectric constant at room temperature $T = 300$ K. The shadow shows the electron-hole single-particle continuum at zero temperature.

Fig. 13 Plasmon spectrum at zero temperature of (A) unbiased (B) $U = 60$ meV biased BLG in vacuum for density $n = 0.1$ (solid), 0.5 (dashed), 1.0 (dotted), and 2.0 (dash-dotted) $\times 10^{12} \text{ cm}^{-2}$. The single-particle continuum at $n = 10^{12} \text{ cm}^{-2}$ is also present (light/dark shadow for the inter-/intra-band part).

Fig. 14 Plasmon spectrum of biased and doped BLG with $U = 30$ meV and $n = 10^{12} \text{ cm}^{-2}$ at room temperature $T = 300$ K in environment of different background dielectric constants ϵ_b . The inset shows the zoomed spectrum of the plasmon branches ω_O , ω_3^p , ω_4^p , and ω_A for $\epsilon_b = 1$ at small q . The light (dark) shadow shows the interband (intraband) single-particle continuum at zero temperature.

to zero, a favorite situation for the stimulated plasmon emission (Rana, 2008). For large q , when the optical plasmon branch enters the interband single-particle continuum, i.e. $\omega_O > \omega_1$, the effect of interband contribution decreases and the plasmon spectrum has a long tail in unbiased system or when the carrier density is high. However, in biased systems with low carrier density, the effect of the interband contribution can be significant due to the flat band and the plasmon spectrum ends near where the intra- and inter-band single-particle continua meet at $\omega_u = \omega_1$.

The competition between the intra- and inter-band contributions may result in two extra plasmon modes for proper U at finite temperature when thermal excitation becomes important as previously discussed in Fig. 11. This is an interesting phenomenon because those modes have unique properties and might be used in nanotechnology. In Fig. 14, we plot the plasmon spectra of a biased system with $U = 30$ meV at $T = 300$ K and $n = 10^{12} \text{ cm}^{-2}$ for background dielectric constant $\epsilon_b = 1$ (solid), 5 (dash-dotted), and 15 (dotted). At room temperature $T = 300$ K, the electronic system is not degenerate and the plasmon spectrum is in general similar to the one of intrinsic BLG as shown in Fig. 12B. However, as shown in Figs. 10 and 11, the interband contribution adds a sharp peak at ω_2 which is around U for small q . As a result, the plasmon spectra are deformed at ω_2 and bifurcate in some cases where two extra plasmon modes ω_3^p and ω_4^p emerge as shown in the inset of Fig. 14.

The emerged two plasmon modes have almost zero group velocities and their frequencies are proportional to the bias voltage. In addition, their energies are in the gap of the zero-temperature single particle continuum and the lower one is below the lower limit of single-particle excitation, ω_2 , at high temperature. This suggests that the modes are undamped or weakly damped and have long lifetime. These undamped plasmon modes are similar to those in MLG but have lower group velocity. Their energies can be easily manipulated by the bias voltage. These undamped modes with almost zero group velocities.

Conclusion

The Coulomb screening properties and the collective excitation modes in monolayer and bilayer graphene are discussed in the random phase approximation. In intrinsic monolayer graphene there is no collective excitation at zero temperature. A potential bias between the sublattices transfers the semimetal to a narrow gap semiconductor system and opens a gap between the intra- and the inter-band electron-hole continuum (EHC). At finite temperature or under the gate voltage, the switch-on of intra-band correlation introduces plasmon modes to the system and the interplay between the intra- and interband correlations play an important role in determining the plasmon spectrum. Undamped plasmon modes exist in the EHC gap. In addition, in a gated graphene with net electrons or holes, a EHC gap is formed for $q < k_F$ and an undamped plasmon mode of frequency $\omega \propto \sqrt{q}$ exist in monolayer graphene gas even at zero temperature, similar to the situation in a normal Fermi gas.

In semimetal intrinsic bilayer graphene, the static dielectric constant is much bigger than that in monolayer graphene, due to the existence of four Dirac points in each energy valley and the much lower 'light' velocity of the Dirac points than the one in monolayer graphene. The Coulomb screening also shows a strong anisotropy. The dynamic Coulomb screening has the characteristics of a Dirac gas on the low energy side and those of a normal Fermi gas on the high energy side. This transition from the Dirac to a Fermi

gas is also reflected in the plasmon dispersion as the wavevector or the energy increases from zero. In doped bilayer graphene, the long wavevector limit of plasmon spectrum is the same as in normal two-dimensional Fermi gas with two valleys.

A potential bias between the two monolayer in bilayer graphene opens a gap between the conduction and valence bands and increases the DOSs at the band edges. As a result, the bias modifies the dielectric function greatly. In the long-wave limit, a sharp and controllable dielectric peak might appear at the energy equal to the band gap at high temperature when the system is nondegenerate or at the energy of double the Fermi energy at low temperature when the system is degenerate. In some cases, two extra undamped plasmon modes appear at energies close to the band gap energy and have almost zero group velocities.
